Those who are familiar with the literature of malignant neoplasms will recall the many valuable contributions that Mr. Sutton has made to it during the past eight years, and it is not a matter of surprise that he should have concluded to formuate his studies in this volume, in which he draws upon his wide knowledge of human and comparative pathology as well as of animal morphology. Indeed, he says that without the aid of comparative pathology any attempt to catch the deeper meaning of many tumors is as difficult as an endeavor to decipher a palimpsest in which the first characters, written in an unknown

tongue, have been imperfectly removed from the parchment and are allowed to mingle with the second inscription.

He considers that the terms scirrhus, colloid, and medullary or encephaloid have dominated the minds of surgeons and hindered progress long enough; and he employs the term cancer in a sense equivalent to malignant adenoma, the species being determined by the gland in which the cancer arises. The confusion that prevails in oncological literature in regard to the use of such terms as classes, groups, species, varieties, etc., seems to Mr. Sutton to be due to the want of even a moderate acquaintance with systematic zoology, for the zoologist at least uses these terms in a consistent manner. The author arranges tumors in four groups: Connective-tissue tumors, epithelial tumors, dermoids, and cysts. Each group contains several genera, each genus has one or more species, and of each species there may be one or more varieties. The connective-tissue group contains lipomata, chondromata, osteomata, odontomata, fibromata, myxomata, gliomata, sarcomata, myomata, neuromata, angeiomata, and lymphangeiomata. The second, or epithelial group, includes papilloma, epithelioma, adenoma, and carcinoma. The third, or dermoid group, includes the genera sequestration dermoids, tubulo-dermoids, ovarian dermoids, and dermoid patches. The fourth, or cyst group, contains the genera retention cysts, tubulo-cysts, hydroceles, and gland cysts, and there is a sub-group of pseudo-cysts, including diverticula, bursæ, natural cysts, and parasites.

Most of these genera are considered in separate chapters, and a comprehensive survey of the species and varieties is a feature of the volume. Take, for example, the chapters on sarcomata; the species round-celled sarcoma, lympho-sarcoma, spindle-celled sarcoma, myeloid sarcoma, alveolar sarcoma, and melano-sarcoma are first described; reference is then made to the infiltrating properties and burrowing tendencies of sarcomata; the secondary changes occurring in these neoplasms are mentioned; and then sarcomata of different tissues are discussed at sufficient length.

In the chapter on the ætiology of tumors the author suggests that it is desirable to arrange tumor germs in two groups—vestiges and rests. The former term he reserves for structures that are remnants of organs functional in vertebrates lower than man, while rests should be reserved for detached fragments of glands and isolated portions of tissue and epithelium. He believes that there are many facts that indicate that cancer is induced by minute parasites. Agreeing with many pathologists that tumors, innocent and malignant, are local troubles, the author urges that the safest and most effectual method of desling with them is expressed in the sentence thorough removal of the tumor, whenever this is possible, at the earliest possible mo-

The book is beautifully illustrated, and it will undoubtedly be accepted as the latest and most authoritative exposition of neoplasms.

Anomalies of Refraction and of the Muscles of the Eye. By FLAVEL B. TIFFANY, M. D., Professor of Ophthalmology and Otology in the University Medical College of Kansas City, Mo., etc. Author's Edition. Kansas City: Hudson-Kimberly Publishing Co., 1894. Pp. viii-7 to 307.

This is the most recent addition to the lost of small works which attempt to present in brief space the science of ophthalmology. Most of the subject can be found as well if not better treated in a large number of books, foreign and domestic, while the recent advancements referred to are very doubtful in character, and not yet sufficiently proved to be advancements to be worthy of introduction as such into a text-book. One would think that in so small a work on so great a subject repetition

would certainly be avoided, but the constant repetitions in this book are very wearisome. As two examples from many, the prisoptometer is figured and described on page 94 and on page 191, the pupillometer is figured and its use explained on pages 92 and 150. The book is not a very necessary addition to our libraries.

Clinical Diagnosis. By Albert Abrams, M. D. (Heidelberg), Professor of Pathology, Cooper Medical College, San Francisco, etc. Third Edition, revised and enlarged. Illustrated. New York: E. B. Treat, 1894. Pp. xi-273. [Price, \$2.75.]

This little book, the third edition of which is now issued, is intended by its author to serve as "an index to or abstract of more pretentious works on the subject," and this it does very well, giving to those who may not possess the more important works of von Jaksch, Vierordt, or Da Costa all the essentials of clinical diagnosis.

In this edition all the latest methods of diagnosis, such as the use of the hæmatocrite, the centrifugal machine, and antral transillumination, are described.

#### BOOKS, ETC., RECEIVED.

Clinical Manual for the Study of Diseases of the Throat. By James Walker Downie, M. B., Fellow and Examiner in Aural Surgery for the Fellowship of the Faculty of Physicians, etc. New York: Macmillan & Co., 1894. Pp. xi-268. [Price, \$2.50.]

Pain in its Neuro-pathological, Diagnostic, Medico legal, and Neuro-therapeutic Relations. By J. Leonard Corning, A. M., M. D., Consultant in Nervous Diseases to St. Francis Hospital, etc. Illustrated. Philadelphia: J. B. Lippincott Company, 1894. Pp. 7 to 328. [Price, \$1.75.]

A Manual of Practical Obstetrics. By Edward P. Davis, A. M., M. D., Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic, etc. Second Edition, revised and enlarged. With One Hundred and Thirty four Illustrations and Sixteen Full-page Plates, several of which are Colored. Philadelphia: P. Blakiston, Son, & Co., 1894. Pp. xii-9 to 351. [Price, \$2.50.]

Disease and Race. By Jadroo. London: Swan, Sonnenschein, & Co., 1894. Pp. vi-121.

On the Features which distinguish Epidemic Roseola (Roserash) from Measles and from Scarlet Fever. By Clement Dukes, M. D., B. S. Lond. London: J. & A. Churchill, 1894. Read before the Members of the Medical Officers of Schools' Association a heir Meeting on February 21, 1894.

Early Operations in Head Injuries. By William B. Van Lennep, M. D., Philadelphia. [Reprinted from the Medical Century.]

Some Considerations bearing upon Practice with Dynamic Antagonists in Cases of Drug-poisoning. By Charles S. Mack, M. D. Mich. [Reprinted from the North American Journal of Homeopathy.

Contribution to the Study of Cerebral Surgery, based on an Operation for the Removal of a Tumor. By M. H. Richardson, M. D. Harvard University, and G. L. Walton, M. D. Harvard University. [Reprinted from the American Journal of the Medical Sciences.

Remarks upon Appendicitis, based upon a Personal Experience of One Hundred and Eighty-one Cases. By Maurice H. Richardson, M. D., Boston. [Reprinted from the American Journal of the Medical Sciences.]

Essentials of Practice of Pharmacy. Arranged in the Form of Questions and Answers. Prepared especially for PharmaSayre, Ph. G., Professor of Pharmacy and Materia Medica, of the School of Pharmacy of the University of Kansas. Philadelphia: W. B. Saunders, 1894. Pp. ix-17 to 200. [Price, \$1.] [Saunders's Question Compends.]

The Second Annual Report of the Sheppard Asylum, a Hospital for Mental Diseases. Baltimore, Md., 1894.

De l'éclairage des cavités de la face. Par le Dr. Maurice à Court Tucker, Paris.

The Conquest of Death. By Abbot Kinney. New York, 1893. Pp. ix-259.

A Modern Wizard. By Rodrigues Ottolengui. New York and London: G. P. Putnam's Sons, 1894. Pp. 434.

A Manual of Nursing in Pelvic Surgery. By Lewis S. Mc-Murtry, A. M., M. D., Professor of Gynæcology in the Hospital College of Medicine, Louisville, Ky. Louisville: John P. Morton & Company, 1894. Pp. 6-7 to 92.

Hydatid Disease. Volume II. By the late John Davies Thomas, M. D. (Lond.), F. R. C. S. (Eng.), formerly Physician to the Adelaide Hospital, etc. A Collection of Papers on Hydatid Disease. Edited and arranged by Alfred Austin Lendow, M. D. (Lond.), etc. Sydney: L. Bruck, 1894. Pp. xii-3 to 166. [Price, 5s.]

A Contribution to the Pathology of Acne Varioliformis Hebræ. By John A. Fordyce, M.D. [Reprinted from the Journal of Cutaneous and Genito-urinary Diseases.]

Memoir of the late Alfred Ludlow Carroll, M. D. By John W. S. Gouley, M. D.

Recurrent Appendicitis. Six Operations with Six Recoveries: Treatment for Acute Attack in Five Cases. By S. C. Gordon, M. D., Portland, Me. [Reprinted from the Boston Medical and Surgical Journal.

Salines in Appendicitis. By S. C. Gordon, M. D., Portland, Me. [Reprinted from the Boston Medical and Surgical Journal.]

Sixty-seventh Annual Report of the Directors of the General Hospital Society of Connecticut. For the Year 1893.

Report of the Jefferson Medical College and Hospital. For the Year ending September 30, 1893.

Sixteenth Annual Report of the Connecticut State Board of Health, for the Year ending June 30, 1893, with the Registration Report for 1892 relating to Births, Marriages, Divorces, and Deaths.

Vexed Questions in the Bacteriology of Diphtheria. By Walter F. Chappell, M. D., New York.

Short Notes of Unusual Cases. By Walter F. Chappell, M. D., New York. [Reprinted from the Annals of Ophthalmology and Otology.

The Prevention of Disease. By De Lancey Rochester, M. D., Buffalo, N. Y. [Reprinted from the Buffalo Medical and Surgical Journal.

Two Cases of Congenital Hypertrophy of the Tongue. A Case of Tuberculosis of the Thyreoid Gland. By Walter F. Chappell, M. D., New York. [Reprinted from the Manhattan Eye and Ear Hospital Reports.]

# Miscellany.

The Ohio State Medical Society will hold its forty-ninth annual meeting at Memorial Building, Zanesville, on May 16th, 17th, and 18th, under the presidency of Dr. N. P. Dandridge, of Cincinnati. The programme includes the following papers: centical Students. Second Edition, revised. By Lucius E. The Physician, by Dr. Samuel Hart, of Marietta; The University and Medical Education, by Dr. D. S. Kellicott, of Columbus; The Prevention of Consumption, by Dr. C. O. Probst, of Columbus; Infection in Tuberculosis-Food Products, by Dr. H. H. Spiers, Rayenna; Is Consumption Curable? by Dr. R. E. Chambers, of Chandlersville (to be discussed by Dr. D. N. Kinsman, of Columbus, and Dr. A. J. Irwin, of Mansfield); La Grippe in the Differential Diagnosis of Scarlet Fever, Measles, and Rötheln, by Dr. James L. Tracy, of Toledo; Scarlatina, by Dr. Amelia J. Prior, of Cincinnati; Diphtheria, by Dr. J. S. Haldeman, of Zanesville (to be discussed by Dr. E. W. Mitchell, of Cincinnati); The Prevention of Pertussis, by Dr. George M. Clouse, of Columbus; Studies in the Ætiology of Small-pox, by Dr. J. C. Graham, of Columbus; The Value of Recent Therapeutic Literature, by Dr. W. C. Chapman, of Toledo; Certain Entozoa of the Dog and the Sheep, by Dr. D. S. Kellicott, of Columbus (to be discussed by Professor J. P. McMurrich, of Cincinnati); On imparting Rudimentary Knowledge to Lawyers, by Dr. Daniel Milliken, of Hamilton; Unjust Malpractice Suits-Causes and Prevention, by Dr. William Estep, of Loydsville; A Year's Operations for Appendicitis, by Dr. Dudley P. Allen, of Cleveland; A Case of Cirsoid Aneurysm, by Dr. W. D. Hamilton, of Columbus; A Case of Cirsoid Aneurysm, by Dr. L. S. Holcomb, of Pennsville; A Case of Aneurysm by Anastomosis, by Dr. J. C. Crossland, of Zanesville; Splenectomy, with the Report of a Successful Case, by Dr. W. J. Conklin, of Dayton; Nephrectomy for Tuberculosis, by Dr. R. Harvey Reed, of Columbus; Gastrostomy-a New Method, by Dr. M Stamm, of Fremont; The Radical Cure of Hernia, by Dr. F. C. Larimore, of Mount Vernon (to be discussed by Dr. F. F. Lawrence, of Columbus): The Treatment of Uterine Fibroids as Indicated by their Natural History, by Dr. C. A. L. Reed, of Cincinnati: Some Remarks on the Total Extirpation of the Fibroid Uterus, with Illustrative Specimens, by Dr. Rufus B. Hall, of Cincinnati (to be discussed by Dr. T. A. Reamy, of Cincinnati); Total Extirpation of a Pregnant Myomatous Uterus, with Specimen, by Dr. C. N. Smith, of Toledo; Hysterorrhaphy the Cure for Retrodeviation of the Uterus, by Dr. F. D. Brandenburg, of Cleveland (to be discussed by Dr. D. Tod Gilliam, of Columbus); Practical Application of the Principles of Sterilization, by Dr. Hunter Robb, of Baltimore (to be discussed by Dr. J. F. Baldwin, of Columbus); Obstetrical Operations involving the Mutilation and Death of the Fœtus, by Dr. E. Gustay Zinke, of Cincinnati; The Treatment of Fractures in the Light of Advanced Histology and Pathology, by Dr. Donald Maclean, of Detroit (to be discussed by Dr. P. S. Connor, of Cincinnati); Studies in the Immunity and Treatment of a Specific Fever-i. e., Hog Cholera, by Dr. D. N. Kinsman, of Columbus; Is there a Better Remedy in Cholera? by Dr. E. B. Fullerton, of Columbus (to be discussed by Dr. A. M. Bleile, of Columbus); The Rationale of Systematic Elimination in the Treatment of Typhoid Fever, by Dr. Robert Peter, of Canal Dover; Typhoid Fever, by Dr. John E. Woodbridge, of Youngstown; The Modern Treatment of Typhoid Fever, by Dr. Howard Jones, of Circleville (to be discussed by Dr. G. A. Collamore, of Toledo, and Dr. Edward Cass, of Dresden); Syphilitic Spinal Paralysis, by Dr. C. J. Aldrich, of Cleveland; Multiple Neuritis, by Dr. Joseph Eichberg, of Cincinnati; The Symptomatology of Hereditary Syphilis, by Dr. R. C. Longfellow, of Cincinnati; Acute and Chronic Diseases, by Dr. J. R. Black, of Newark; Pneumonia, by Dr. A. E. Bell, of Zanesville; The Pheuomena of Fertilization and their Bearing on Heredity, by Dr. J. Playfair McMurrich, of Cincinnati; Diseases of a Reflex Nature arising from Pathological Conditions of the Uterus and Appendages, by Dr. William H. Humiston, of Cleveland; The Importance of Determining Reflex Irritation in Catarrhal Processes, by Dr. J. P. Sawyer, of Cleveland (to be discussed by Dr. T. M. Sabin, of

Warren); The Effect of Obstructive Disease in the Upper Airpassages on the General Health, by Dr. J. A. Thompson, of Cincinnati; Headache, its Relation to Optical and Muscular Defects of the Eyes, by Dr. S. C. Ayres, of Cincinnati (to be discussed by Dr. A. R. Baker, of Cleveland); Sympathetic Ophthalmia, by Dr. B. F. Templeton, of Zanesville (to be discussed by Dr. H. P. Allen, of Columbus); Diseases of the Cornea in Childhood, by Dr. C. W. Tangeman, of Cincinnati (to be discussed by Dr. Francis Dowling, of Cincinnati); The Use of Plaster in Joint Diseases, by Dr. T. C. Hoover, of Columbus; Subcutaneous Osteotomy, with Cases-a New Osteotome, by Dr. Willis W. Hall, of Springfield (to be discussed by Dr. S. S. Thorn, of Toledo); Subluxation of the Knee, with Treatment, by Dr. S. L. McCurdy, of Dennison; Fractures of the External Condyle of the Humerus, by Dr. F. E. Bunts, of Cleveland (to be discussed by Dr. F. D. Bain, of Kenton); Practical Points in Ether Anæsthesia, by Dr. W. D. Porter, of Cincinnati; Rectal Abscess, by Dr. Auguste Rhu, of Marion; Trephining, with a Report of Cases, by Dr. Leonard Freeman, of Cincinnati (to be discussed by Dr. S. F. Forbes, of Toledo); Middle Florida as a Winter Resort for Invalids, by Dr. F. D. Case, of Ashtabula; Tonsillitis, by Dr. H. J. Noyes, of McConnellsville; A Case of Myxœdema, by Dr. E. M. Fitton, of Hamilton; Valvular Disease and Chronic Rheumatism, by Dr. W. W. Pennell, of Frederickstown: The Local Treatment of Cystitis, by Dr. G. W. Morehouse, of Sparta; and Cremation as a Means of Practical Sanitary Reform, by Dr. Charles P. King, of Newark.

The Association of American Physicians will hold its ninth annual meeting in Washington, in the Columbian University, on Tuesday, Wednesday, Thursday, and Friday, May 29th, 30th, and 31st, and June 1st, under the presidency of Dr. Reginald H. Fitz, of Boston, and in connection with the third Congress of American Physicians and Surgeons. Besides the president's address, the programme includes the following titles:

The Treatment of Certain Symptoms of Croupous Pneumonia, particularly in Adults, by Dr. Beverley Robinson, of New York; A Treatment of Typhoid Fever, by Dr. Samuel A. Fisk, of Denver; Six Cases of Traumatic Headache, by Dr. C. F. Folsom, of Boston; A Clinical Report of Two Cases of Raynaud's Disease, by Dr. Frederick P. Henry, of Philadelphia; Dr. S. C. Martin's Researches on the Bacteria of Vaccinia, by Dr. Harold C. Ernst, of Boston; Modification, Temporary and Permanent, of Physiological Characters of Bacteria in Mixed Cultures, by Dr. Theobald Smith, of Washington; The Effect of Various Metals on the Growth of Pathogenic Bacteria, by Dr. Meade Bolton, of Baltimore; Note on the Observation of Malarial Organisms in Connection with Typhoid Fever, by Dr. W. Gilman Thompson, of New York; Experiments in Artificial Melanosis, by Dr. George Dock, of Ann Arbor; Stomatitis Neurotica, by Dr. A. Jacobi, of New York; Tetany in America, by Dr. J. P. Crozer Griffith, of Philadelphia; Lead Palsy in Children, by Dr. Wharton Sinkler, of Philadelphia; A Study of the Temperature in Cerebral Apoplexy, by Dr. Charles L. Dana, of New York; The Mild Character and Diminished Prevalence of Syphilis and the Infrequency of Visceral Syphilis, by Dr. John H. Musser, of Philadelphia; Some Remarks on the Significance of Albumin and Casts, especially in those Past Middle Life, by Dr. Frederick C. Shattuck, of Boston; Experimental Phthisis in the Rabbit with Formation of Cavities: A Demonstration, by Dr. T. M. Prudden, of New York; A Report of the Ultimate Results obtained on Experimental Eye Tuberculosis by Tuberculin Treatment and Anti-tubercular Inoculation, by Dr. E. L. Trudeau, of Saranac Lake; Some of the Chemical and Bacteriological Characteristics of Milk, by Dr. Thomas M. Rotch, of Boston: The Chemical Products of the

Anaerobic Putrefaction of Pancreatic and Hepatic Tissues, and their Effects upon the Tests for Morphine, by Dr. Victor C. Vaughan, of Ann Arbor; Gastro-enteric Rheumatism, by Dr. H. M. Lyman, of Chicago; A Case of Osteomalacia, by Dr. George Dock, of Ann Arbor; A Case of Mitral Stenosis with great Hypertrophy of the Right Ventricle: Death from Hæmoptysis, by Dr. A. McPhedran, of Toronto; and A Case of Calculous Pyelitis with Invasion by the Bacillus Lactis Aerogenes, by Dr. J. H. Musser, of Philadelphia.

Tuberculin in the Food of Consumptive Patients. - The allegation has been made that the heat used in cooking tuberculous meat and in boiling or Pasteurizing milk does away with every element of danger by killing the microbes and their spores. Professor James Law, of Cornell University, has stated, however, in a recent number of the Cornell Bulletin, that the cooked meat and milk are still dangerous because of the chemical poisons secreted by the microbes, especially those in the tuberculin. Sterilization is not a restoration to a nonpoisonous condition, for, though the possibility of inoculation is removed, the product is not rendered innocuous. The sterilization of Koch's tuberculin has not by any means rendered it safe and harmless. On the contrary, it invariably intensifies any existing tuberculous process, developing fever and general constitutional disorder. Hence, whenever tuberculin is present in meat or milk, it causes these foods to affect consumptive patients in the same manner. In Professor Law's experience with tuberculosis he has observed cases in which invalids drinking the milk of tuberculous cows suffered very obviously, but as soon as such milk was withheld there was a marked improvement. He noticed that calves sucking consumptive cows did badly and proved unthrifty, though they took all the milk furnished by their respective nurses, but, when weaned and fed on solid food, they thrived much better. He has followed such calves until they grew up and were slaughtered, and found in the post-mortem examinations that they bore old calcified tubercles pointing back to the time when they had sucked the diseased and poisonous milk. K. Yamagiva successfully inoculated guinea-pigs with tuberculosis and afterward administered tuberculin, and found that it so greatly hastened the onset of general tuberculosis that after a week tuberculous centers were found in the lymphatic glands, spleen, liver, and lungs. Human beings are much more susceptible than the guinea-pig to the tuberculin poisons. It may be safely held as proved by analogy, observation, and experiment that the soluble poisons of tuberculosis invariably operate by exaggerating any existing tuberculous process, and that blood and other animal fluids becoming charged with such poisons uniformly tend to further endanger the health and life of any patient who may consume them while suffering from tuberculosis. The germ, especially in the tubercle of this disease, which might have remained comparatively dormant and harmless in the absence of the poisoned meat and milk, is by these stimulated to a more deadly energy.

Hydrocele of the Tunica Vaginalis.—Differences not only in size but also in shape have been noticed in simple hydroceles of the tunica vaginalis. The manner in which the serous membrane is related to the testicle and epididymis in each patient would seem to account for the differences in form of the distended sac. From the study of many such cases, Dr. Joseph Griffiths, of the University of Cambridge (Journal of Anatomy and Physiology, April, 1894), concludes that in the adult the distended tunica vaginalis usually assumes either a spherical or an ovoidal shape. In the child the sac of the tunica vaginalis is almost always of a pyriform shape, with a slight constriction near the upper level of the testis. When

persistence of the condition found in the child or to the incomplete obliteration of the lower end of the processus vaginalis and the occurrence of a free communication between its cavity and that of the tunica vaginalis. The bilocular form of this hydrocele occurs when the processus vaginalis remains unobliterated, being shut off, however, from the peritoneal cavity above, though still communicating with the tunica vaginalis by an opening of variable size, depending upon the degree of the constriction at the line of junction of the processus and the tunica vaginalis. A multilocular variety of this simple hydrocele is occasionally seen in which the locules arise either from bulgings of the serous membrane or from the formation of incomplete sæpta between opposed parts of the parietal and visceral layers.

The Transactions of the Pan-American Medical Congress. —The proceedings of the First Pan-American Medical Congress were compiled by the secretary general, Dr. Charles A. L. Reed, and transmitted to the Department of State in November, 1893. By a recent joint resolution of the Senate and House of Representatives the manuscript was transmitted to Congress and a concurrent resolution has been adopted directing the Public Printer to print the same. The manuscript is now in the office of the Public Printer and will be put to press at once under the supervision of the editorial committee, of which Professor John

The Society of Medical Jurisprudence.-At the next meeting, on Monday evening, the 14th inst., Mr. William George Oppenheim, of the New York Bar, will read a paper entitled A Plea for a National Compulsory Sanitation Law.

Guitéras, of Philadelphia, is chairman.

The American Orthopædic Association.—The eighth annual meeting will be held at the Columbian University, Washington, on May 29th, 30th, and 31st and June 1st, under the presidency of Dr. A. M. Phelps, of New York, in addition to whose address the following papers will be read: The Treatment of Severe Forms of Ciubfoot, by Mr. Edmond Owen, of London; Tarsoclasis for Clubfoot, Mr. Nicholas Grattan, of Cork; The Abuse of Phelps's Operation for Clubfoot, by Dr. James E. Moore, of Minneapolis; Phelps's Operation for Talipes Varo-equinus, by Dr. H. P. Kaptyn, of Abcoude, Holland; Phelps's Method for the Cure of Clubfoot in Adults, by Dr. William E. Wirt, of Cleveland; Phelps's Method of Treating Severe Forms of Clubfoot, by Dr. Cordua, of Hamburg, Germany; The Place of Traction in the Treatment of Clubfoot, by Dr. Newton M. Shaffer, of New York; Elastic Traction in the Immediate Treatment of Clubfoot, by Dr. Bernard Bartow, of Buffalo; Some Observations on the Anterior Transverse Arch of the Foot and its Obliteration as a Cause of Metatarsalgia, by Dr. Joel E. Goldthwait, of Boston; Final Results in One Hundred Cases of Operation for Deformities following Hip-joint Disease, by Dr. V. P. Gibney, of New York; The Treatment of Hip Disease and the Application of Lateral Traction, by Dr. Robert W. Lovett, of Boston; The Question of Priority in the Application of Lateral Traction to Relieve Intra-articular Pressure in Hip-joint Disease, The Presentation of New Knee and Ankle Splints, The New Improved Celluloid Corset, and An Original Operation for Wryneck, by Dr. A. M. Phelps, of New York; Blanchard's Hip Splint, by Dr. Wallace Blanchard, of Chicago; What Results should we try to Attain in the Treatment of Hip-joint Disease? by Dr. Reginald H. Sayre, of New York; Cases of Hoffa's Operation for Congenital Dislocation of the Hip Joint, by Dr. E. H. Bradford, of Boston; Lorenz's Operation for Congenital Dislocation of the Hip, by Dr. A. Lorenz, of Vienna; Congenital Dislocation of the Hip, by Dr. this pyriform shape is found in the adult, it is due either to the T. Halsted Myers, of New York; The Results in Talipes Varo-

equinus after Phelps's Operation, and the Limits of Operative Treatment in Congenital Dislocation of the Hip, by Dr. Sigfred Levy, of Copenhagen; Congenital Dislocation of the Hip, by Dr. L. A. Weigel, of Rochester; Peculiar Nervous Symptoms occurring in Pott's Disease of the Spine, by Dr. Leroy W. Hubbard, of New York; Relief of the Spondylitic Spine from the Concussion of Walking, by Dr. John C. Schapps, of Brooklyn; Spondvlitis, by Dr. A. J. Steele, of St. Louis; The Treatment of Old Neglected Cases of Deformity following Poliomyelitis, by Dr. S. L. McCurdy, of Dennison, Ohio; Observations on Rhachitic Distortions of the Neck of the Femur in Adolescence, and its Significance, by Dr. Royal Whitman, of New York; Infantile Apoplexy and Paralysis, and some of their Consequences, by Mr. W. J. Little, of England; The Ætiology of Deformities in Knee-joint Disease, by Dr. A. E. Hoadley, of Chicago; The Care of the Bony Frame in Infancy and Childhood, by Dr. J. B. Ransom, of Dannemora, N. Y.; Diseases of the Knee Joint, by Dr. J. D. Griffith, of Kansas City; Excision of the Knee for the Relief of Crippling from Infantile Paralysis, by Dr. ApMorgan Vance, of Louisville; The Treatment of Lateral Rotary Curvature of the Spine by Non-restorative and Developmental Methods, by Dr. B. E. McKenzie, of Toronto; The Improved Machine for Treating Scoliosis, by Dr. Max Schede, of Hamburg, Germany; Scoliosis, by Dr. A. B. Hosmer, of Chicago; Excision of the Sac in Spina Bifida, by Dr. De Forest Willard, of Philadelphia; On the Application of the Principle of Extension in the Treatment of Wryneck, by Mr. William Adams and Mr. R. W. de Sante, of London; The Lorenz Osteoclast, by Dr. F. S. Coolridge, of Chicago; A Case of Ankylosis of the Jaw in a Child-Resection and Recovery with Good Motion, by Dr. Dillon Brown, of New York; Excision of the Wrist Joint by a New Method, by Herman Mynter, of Buffalo; Disease of the Shoulder Joint, by Dr. W. R. Townsend, of New York; Fixation and Traction in the Treatment of Fractures into Joints, by Dr. Ansel G. Cook, of Hartford; and papers by Dr. W. J. Taylor, of Philadelphia, Dr. W. O. Plimpton, of New York, and Dr. James Kerr, of Washington (titles to be announced).

Subjects for Discussion .- Flat-foot: Its Ætiology and the Mechanism of its Production, by Dr. Newton M. Shaffer, of New York: Pathology, Prognosis, and Mechanical and Surgical Treatment, by Dr. T. C. Morton, of Philadelphia; Gymnastic Treatment, by Dr. H. Augustus Wilson, of Philadelphia. Dr. Royal Whitman, of New York, Dr. Sidney Roberts, of Philadelphia, Dr. J. D. Griffith, of Kansas City, Dr. Roswell Park, of Buffalo, and others will take part in the discussion. Rhachitic Deformities: Ætiology, Clinical History, and Lesions, by Dr. A. Jacobi, of New York; Its Various Manifestations, Diagnosis, Differential Diagnosis, and Prognosis, by Dr. Benjamin Lee, of Philadelphia; Mechanical and Constitutional Treatment, by Dr. Samuel Ketch, of New York; and Operative Treatment, by Dr. De Forest Willard, of Philadelphia; Paralytic Deformities: Ætiology, Clinical History, and Pathological Conditions producing them, by Dr. E. H. Bradford, of Boston; Varieties, Diagnosis, Differential Diagnosis, and Prognosis, by Dr. E. G. Brackett, of Boston; Mechanical Treatment, by Dr. John Ridlon, of Chicago, and Dr. Joel Goldthwait, of Boston; and Operative Treatment of Paralytic and Rhachitic Deformities, by Dr. De Forest Willard, of Philadelphia.

The Effect of Limewater on the Urine.—As limewater is almost a necessary part of the liquid diet of illness and infancy, it is very important that all its effects upon the system should be known. That the urine is rendered alkaline by an excess of limewater in the food is a frequent clinical observation, but the nature of this alkalinity has only recently been studied. The mother of an infant noticed an ammoniacal odor

coming from its urine-moistened linen, for which the physician could find no other cause than the limewater which had been administered freely in the milk for some months. As a test case, two teaspoonfuls of a very thick cream of lime were well distributed in the milk and other food of a boy, four years old. On the evening of the third day, the child's urine gave off free ammonia, and had all the characteristic reactions of a dilute solution of calcium carbonate. There was no digestive disturbance.

The test was made by Dr. John J. Abel, of the Johns Hopkins Medical School, whose account appears in the Johns Hopkins Hospital Bulletin for April. He further experimented upon healthy animals, and found that when slaked lime was mixed with the food of dogs fed on bone-free meat their urine became strongly alkaline and spontaneously gave off carbon dioxide and ammonia. It contained, however, absolutely less ammonia in the twenty-four hours than normal urine. It always contained a calcium salt in solution which was not bicarbonate of calcium, and which decomposed with precipitation of calcium carbonate when the urine was allowed to stand. This lime urine exhibited all the characteristics of a weak aqueous solution of calcium carbonate, and a white powder was isolated from it which behaved in every way like synthetically prepared calcium carbamate, except that it gave less accurate results when subjected to quantitative analysis. Human urine was found to react exactly like that of the dog, when large quantities of lime were taken in the food, and it likewise contained calcium carbamate. Carbamic acid, which is believed to be one of the principal immediate precursors of urea, combines with the lime, and the human body probably avails itself of the readily soluble carbamate of calcium to eliminate an excess of lime that has been absorbed. It is an interesting fact that so simple a drug as limewater may cause such hitherto unsuspected changes in the urine.

Bacteriological Examinations in Cases of so-called Membranous Croup.—The following report has been made to the president of the Health Department of the City of New York, by Dr. Hermann M. Biggs, pathologist and director of the bacteriological laboratory:

Some months ago I had the honor to present a communication to the board of health directing attention to the results obtained in the bacteriological examination of a considerable number of cases of so-called membranous croup. In that communication it was shown that in a large proportion of these cases bacteriological examination disclosed the presence of the Klebs-Loeffler bacillus of diphtheria, proving that those were really cases of true diphtheria of the laryux. It was further shown by the investigation of the clinical histories of these cases that in many instances there was satisfactory proof that they were cases of diphtheria in which previous and subsequent infection could be traced. Since the former report a large number of further observations has been made which, I believe, justify this department in considering so-called membranous croup as laryngeal diphtheria.

Two hundred and eighty-six cases of so-called membranous croup in children have been examined bacteriologically. In 229 of these cases the characteristic Loeffler (diphtheria) bacilli were found, and these cases were thus proved to be true diphtheria. Of these 229 cases, 167 showed no false membrane or exudate above the larynx, while in the remaining 62, although the larynx was mainly involved, there was also some false membrane present on the tonsils or in the pharynx. Of the 57 cases examined in which no Loeffler bacilli were found, in 17 the cultures were unsatisfactory, leaving the bacteriological diagnosis in these cases doubtful. Of the 40 cases remaining in which

no Loeffler bacilli were found, in 27 the disease was confined to the larynx or bronchi, and in 13 there was also more or less exudate or false membrane present on the tonsils or in the pharenx.

It has been shown, therefore, by these examinations that about eighty per cent. of the cases of so-called membranous croup in children which have been subjected to bacteriological examination in the laboratory of the Health Department during the past ten months were cases of true diphtheria, and of the remaining twenty per cent., six per cent. were doubtful, and only fourteen per cent. were undoubtedly not diphtheria. Further investigations have also shown that cases of pharyngeal diphtheria frequently precede or follow these cases of croup.

Inasmuch, therefore, as so-called membranous croup has been clinically separated from diphtheria, and as cases of this disease are not usually considered as laryngeal diphtheria, and are not reported to the department as diphtheria, I would respectfully recommend that so-called membranous croup be regarded as pharyngeal diphtheria, and be included in the list of the contagious diseases concerning which reports are required from physicians of this city.

The American Association of Genito-urinary Surgeons.

-The eighth annual meeting will be held at the Shoreham Hotel, Washington, on May 29th, 30th, and 31st and June 1st, under the presidency of Dr. George Chismore, of San Francisco. The programme includes the following papers: A Modification of Bigelow's Operation for Stone in the Bladder, designed to meet Cases in which the Prostate is Enlarged, by Dr. George Chismore, of San Francisco; The Treatment of the Hypertrophied Prostate, by Dr. J. William White, of Philadelphia; A Suggestion as to the Best Method of Removing Fibroadenomatous Growths from the Prostate, by Dr. Samuel Alexander, of New York; A Report of some Cases of Rupture of the Urethra, by Dr. Francis S. Watson, of Boston; Remarks on the Treatment of Cystitis, by Dr. Gardner W. Allen, of Boston; The Treatment of Imperfect Transition of the Testes, by Dr. Samuel Alexander, of New York; Aero-urethroscopy with a New Instrument, by Dr. William K. Otis, of New York; New Instruments and Apparatus, by Dr. F. Tilden Brown, of New York; Stone in the Bladder-Choice of Operation, by Dr. William H. Hingston, of Montreal; Urine Leakage and Stricture Formation, by Dr. John P. Bryson, of St. Louis; The Possibility of Overcoming Permanent Stricture of the Deep Urethra without Resort to External Urethrotomy, by Dr. J. Blake White, of New York; The Surgical Aspect of Impotence, by Dr. Edward R. Palmer, of Louisville; Epithelioma of the Penis, by Dr. Edward Martin, of Philadelphia; The Hygiene of Circumcision, by Dr. W. Frank Glenn, of Nashville; The Question of Surgical Interference in Tuberculous Kidney, by Dr. John P. Bryson, of St. Louis; A Brief Report of a Case of Cystitis and Pyelonephritis due to the Colon Bacillus, requiring Nephrectomy, by Dr. F. Tilden Brown, of New York; A Report on Irrigation of the Bladder and Urethra without a Catheter, by Dr. George F. Brewer, of New York; Catheterism of the Ureters in the Male, by Dr. William K. Otis, of New York; Exhibition of a Calculus from the Kidney, by Dr. Edmund E. King, of Toronto; Some Infrequent Symptoms of Disease of the Urinary Tract, by Dr. Alexander W. Stein, of New York; The Relationship of Syphilis to Stricture of the Rectum, by Dr. Robert W. Taylor, of New York; Two Cases of Syphilis having a Bearing on the Question of the Period during which the Disease is Communicable, by Dr. James Bell, of Montreal; and Excision of the Initial Lesion, by Dr. Edmund E. King, of Toronto. In addition there will be discussions on Nephritis in its Surgical Aspects (to be opened by Dr. Edward L. Keyes, of New York), and on the Bacteriology of Nephritis (to be opened by Dr. George M. Sternberg, of the army).

Pharmacy as a Profession.—This was made the subject of a valedictory address to the class of 1894 of the Philadelphia College of Pharmacy, by Samuel P. Sadtler, Ph. D., the professor of chemistry, which is published in the May number of the American Journal of Pharmacy. In the course of his remarks Professor Sadtler said:

"Another of the drawbacks to the proper recognition of pharmacy as a profession is the comparison so often drawn between it and the related profession of medicine, and drawn, I need hardly say, in most cases to the disadvantage of the former. It is not alone drawn by the doctor, who from the time he leaves the medical college calmly draws a line between himself and the 'laity,' as he calls the rest of the world. This superiority of the medical profession is too often conceded as a matter of course by the pharmacist, who feels the necessity of gaining the good will of the medical profession living in his neighborhood as a question of business. Is it any wonder then that the public take him at his own estimate, and grow accustomed to give a respect to the one profession that they deny to the other? This difference in valuation is only encouraged when the pharmacist proceeds to demonstrate his belief in it by taking up medical studies, even after years of practical business life, and adding the medical degree to that of graduate in pharmacy. I do not wish to be misunderstood here. Many young men enter upon the study of pharmacy, and pursue it diligently, with the full intention from the beginning of following it by studies in medicine. For such a plan I have nothing but commendation. I have repeatedly heard medical men, who had pursued this plan, acknowledge the invaluable aid that the thorough grounding in a knowledge of drugs and medicines and their preparation acquired in a college of pharmacy gave them in the after practice of medicine. But can not the graduate in pharmacy, who has had no such plan of study, who has only started out to acquire a pharmaceutical education, feel that he has a worthy profession before him, if he will but strive to make himself worthy of it? He has had an insight during his college years into the methods of work in chemistry, both analytical and synthetical, in operative pharmacy, the field of which is becoming wider every day, in microscopical study of plant tissue and drug structure. Is there, then, nothing that promises results for him in all this, results that will bring him both pecuniary reward and reputation ? "

"Quacks."—The British Medical Journal quotes from the Pall Mall Gazette the following supposed correspondence between Lady Morgan and the late Dr. Jenner:

"Pve dispatched, dear Lady Morgan, this scrap of a letter To say that Miss Charlotte is certainly better. A regular doctor no longer she lacks, And therefore Pve sent her a couple of quacks," (With the note came a couple of wild ducks.)

Lady Morgan's reply:

"Yes, 'twas politic truly, my very good friend,
Thus a couple of quacks your patient to send,
Since there's nothing so, likely as quacks, it is plain,
To make work for a regular doctor again."

Senecio Jacobæa as an Emmenagogue.—In the British Medical Journal for March 31st Dr. William Murrell gives his experience in the use of this plant, the common ragwort or liferoot, as an emmenagogue. He began with half-drachm doses of a one-to-ten tincture, in water, three times a day, and, experimenting on himself to ascertain the quantity that it was

safe to take, gradually increased the dose to half an ounce four times a day for a month, without producing any effect. He then began giving it to women suffering from menstrual derangements, and found that it answered well in cases of amenorrhea. His use of the plant was not limited to the tincture; in many cases he employed a one-to-one fluid extract, and he thinks that this fluid extract may sometimes have been prepared from Senecio aureus (an American species); but he does not think that the substitution of one species for the other is an important matter, as they both seem to have the same action. He has also used with good results the active principle, senecin, a dark, resinous-looking substance, the minimum dose of which is two grains three times a day. He has found senecio useful in cases in which menstruation, having been performed regularly for some years, has suddenly been suspended as the result of exposure to cold. In the majority of cases the function is not re established until the drug has been taken for ten days or a fortnight; but in one case, after two periods had been missed, the patient became unwell after taking six two-drachm doses. As a rule, only a drachm, three times a day, was given to begin with, and the dose was increased gradually; but the author says that it is perfectly safe to begin with two-drachm doses of the tincture or twenty-minim doses of the fluid extract four times a day. These preparations, he says, are taken without difficulty, and do not cause either purging or vomiting. In some cases in which the amenorrhoea was associated with decided anæmia the drug failed. In some of these cases menstruation was restored by giving iron, but when that drug failed senecio answered well. Sometimes senecio is useful in cases in which menstruation has never been established. Dr. Murrell is satisfied that senecio not only hastens the occurrence of menstruation, but also increases the flow. In many cases it relieves the accompanying pain and frequently the headache. In one case a profuse leucorrhœa of many months' duration disappeared coincidently with the administration of the drug. The author has very little doubt that senecio deserves to rank with permanganate of potassium and binoxide of manganese as an emmenagogue.

Secondary Fever in Scarlatina without Local Complications .- In the April number of the Quarterly Medical Journal for Yorkshire and Adjoining Counties, England, Dr. E. Wearne Clarke relates the case of a little girl, seven years old, who was attacked with scarlet fever of moderate severity presenting at the outset the ordinary features. The temperature rose rapidly to 104.2°, the rash was generalized and tolerably profuse, and the sore throat was of very moderate intensity. There was a certain amount of mild delirium at night. The rash began to fade on the fourth day of observation and simultaneously the temperature fell to 100.8°. Two days later it rose again rapidly to 102.8°, and remained elevated for ten days, ranging between 100° and 101° in the morning and between 102° and 102.8° in the evening most of that time, the maximum being usually attained at or soon after six o'clock in the afternoon. On the seventh day of this renewed fever, at 5.55 p. m., when the temperature was 101.8° and apparently tending toward the usual evening rise, five grains of antipyrine were given and a little later a cold pack was administered. At ten o'clock the temperature was 100 8° and at four o'clock in the morning it was 98.2°. By 1.15 P. M., however, it had risen to 101°, and at 6 P. M. it was 100.8°. The next morning it was 99.4°, and rose to 100 8° in the evening. A like rise occurred on the following evening, and after that there was a fall to 98°, with never again any elevation. All this time desquamation was proceeding rapidly, and no local complication that could account for the rise of temperature was observed. In spite of the fever, the

child's general condition was good; the urine was abundant throughout and contained no albumin. The subsequent progress of the case was favorable. Dr. Clarke is inclined to think, with Bouveret, that in such cases the continuance of fever is due to the action of a toxine of scarlatinal origin, probably producing a disturbance of the nervous centers. The article is illustrated with a temperature chart.

Ether as an Anæsthetic.- In the March number of the Australasian Medical Gazette there is an editorial article suggested, the writer says, by certain recent investigations as to the physiological action of chloroform, with deductions as to the precautions to be taken to avoid disaster from its use as an anæsthetic. The writer takes the ground that, while such experimental investigations may serve to explain how disasters and narrow escapes are brought about, it is to be feared that no such practical result has ensued as a diminution of the mortality attending chloroform inhalation. It has lately been declared by a Melbourne physician that the death-rate in Victoria from snake-bite is smaller than that in Melbourne alone from chloroform inhalation, and some go so far as to say that in cases where death has occurred from the inhalation of chloroform, the administrator should be put upon trial for malpractice or manslaughter. Although the writer does not indorse such extreme views, he certainly thinks it strange that the medical profession at large hesitates to recommend the substitution of ether for chloroform as the anæsthetic for general use. Accidents with ether are very seldom heard of, and the purity of that drug may readily be ascertained by a competent analyst, whereas the deadly impurities of chloroform baffle analysts and require the aid of the physiological chemist for their detection. In Australia the experience of those who use ether most teaches that very few patients are unsuitable subjects for its administration, and it is believed that its after-effects are neither so serious nor so unpleasant as to justify the use of a drug which, even in skilled hands, is so unsafe as chloroform, simply because the latter is less unpleasant to take and possibly more pleasant to recover from. In conclusion, the writer says that at the recent intercolonial congress much was said in defense of chloroform, and he asks if this fact was an illustration of the proverb qui s'excuse s'accuse.

Lawsonia Inermis. - In the April number of the Archives de médecine et de pharmacie militaires M. Ehrmann, a military pharmacist, publishes a study of this plant, the hanneh of the Arabs, who look upon it as a panacea: The author briefly enumerates the uses of the plant in Arabic medicine. Fissures are treated with a mixture of powdered lawsonia and powdered alum. Chancres and other ulcerations are covered with the powdered plant, and the itch is treated in the same way. The drug is employed topically as a remedy for engorgement of the lower limbs complicated with ulceration. As an application to wounds it is considered tonic and astringent. Wounds with great loss of substance are treated by means of quantities of the plant, and the dressing is renewed once in three days. Contused wounds are treated with the leaves beaten and moistened with a little water. Migraine is treated with poultices containing the seeds and black anise. Diarrhea is cured with a weak decoction of the plant. The flowers, in infusion, are remedial in migraine and in bruises; a perfumed oil prepared from them is used as a cosmetic. An Arabian remedy for sterility consists in smelling of the fresh flowers. A few leaves of the plant cast into a cup of boiling water form a drink which is believed to ward off all the unpleasant consequences of abortion. The bark, in decoction, is used for jaundice, inflammation of the liver, calculous affections, leprosy, and diseases of the spinal cord. The fruit is considered emmenagogue.

FISH BONES IN THE THROAT,

AND WHAT THEY SUGGEST CONCERNING DEGLUTITION.\*

BY ADOLPH RUPP, M.D.

I. Frequency and Diagnosis.—Some authors who have written on foreign bodies in the throat have said nothing concerning the question, How came those foreign bodies to be lodged at or in the particular places where they are found? Others have given only a partial and inadequate answer, based on reasoning of secondary importance at best, and which, in some respects, implies a misconception of the anatomy and physiology of the throat.

In this paper I do not propose to discuss those substances which give rise to obstructive symptoms on account of their bulk, but only of fish bones and similar sharp-pointed and slender substances, such as pins and needles, splinters of wood, etc.

My reason for limiting the discussion to these substances is that they usually have the quality of staying where they become fixed or lodged, but more particularly because they lend themselves very well in the way of illustration for answering the question, How came these foreign bodies to be lodged or fixed in or at the particular places where they are found? The answer to this question involves problems of deglutition, as well as secondary questions of pathology, anatomical peculiarities, and personal habits. Foreign bodies-fish bones, needles, etc.-so lodged in the throat as to demand surgical assistance in their removal are, comparatively speaking, very rare accidents. During over one years' service in the throat and ear class of the Northern Dispensary of this city, during the years 1881 and 1882, I saw only one case-and then the fish bone was as much in the larynx as in the pharynx. In private practice during a period of thirteen years, I removed four fish bones from the throats of as many patients. At the New York Eye and Ear Infirmary during five years (1885, 1887, 1888, 1889, and 1890) seven thousand eight hundred and forty patients applied at the Throat Department for treatment. None of these patients had any foreign body in the pharynx, palate, fauces, or tonsils-that is to sav, in the throat. Fifteen of these patients had foreign bodies in the larynx, and in sixteen patients foreign bodies were found in the nasal cavities. At the clinic of Professor Jurasz (1), at Heidelberg, during a period of about seven years and a half, four thousand and forty-eight patients were treated for the various troubles of the upper respiratory organs. Nineteen of these patients, ranging in age from four years to sixty-eight years, applied to have foreign bodies taken from their throats; but in only four of the throats could a foreign body be found after careful examination. During a period of ten years, Schäffer (2), of Bremen, met with foreign bodies in the throat only seven times in as many patients, and six times the foreign bodies were fish bones.

Although not a frequent it is a common experience to be called on to remove foreign bodies from the throats of patients-children as well as adults-when really none are present or discoverable. In cases where no foreign bodies are present the pain and discomfort will be found to be due to local trouble of some kind. These patients are not necessarily hysterical and neurasthenic people. In my experience they have been people addicted to tobacco and alcohol excesses. A history of foreign body may or may not be given when a foreign body is or is not present. Whatever the case may be, a careful and thorough examination should always be made. I have been called three times to treat children who it was supposed had pins and bones in their throats. In one of these cases the child, nine months old, was supposed to have swallowed an open diaper pin. The pin had been mislaid by the mother, and was afterward found in a safe place-not in the child. Another child, not quite a year old, swallowed part of the spinal column of a herring. This causing choking symptoms, the father looked for the trouble in the throat, and luckily pushed the vertebra down the child's œsophagus. These bones were passed per anum next day. The third case was one of fright and suspicion and developed nothing more. Cases in children, easy enough to diagnosticate and easy enough to treat when due care is exercised, may lead to grave results if handled carelessly or in ignorance of a practical knowledge of this subject. Thus Walter F. Atlee, M. D., tells of the case of a seventeen-months-old child that lost its life, he reports, because "a well-known and experienced physician" made only an imperfect examination, and treated the child for a simple angina by giving a harmless chlorate-of-potassium mixture. In the course of four or five days the symptoms became alarming, and Dr. Atlee was called in to see the case. He found, on passing his finger into the child's mouth and throat, a pin firmly fixed between the right faucial pillar by one end, and the other end in the posterior wall of the pharynx. The child died the day after Dr. Atlee removed the pin, and five or six days after the pin had been swallowed.

However, cases occur, now and then, which foil the best efforts of the best-equipped laryngoscopists. O. Chiari (4), (Vienna), narrates the case of a man who swallowed a piece of wooden toothpick which gave rise to swelling of the left half of the velum. After a good deal of trouble and careful search he gave up the hunt, having been unsuccessful. The next day the patient coughed out the splinter spontaneously. Patients have been known to have gone to as many as half a dozen doctors before the site of a foreign body was located. Schäffer tells of such an instance in his experience, and where the foreign body was in one of the vallecules. The following case of an eighteen-months-old child, reported by George White, M. D. (5), (Chicago), is interesting in this respect, and again because of the length of time the pin remained in the child's throat without doing any serious damage-differing in this respect from the case reported by Atlee and just quoted. Several physicians successively had been called in to see the case before Dr. White discovered the pin and its location. Œdema of

<sup>\*</sup> Read before the Laryngological Section of the New York Academy of Medicine, March 28, 1894.

the pharynx had been made the excuse for failure in finding and locating the pin. In this case the pin had been in the child's throat about eight months when Dr. White was called in to see the case. On depressing the child's tongue with his finger, the little one retched, and, looking into the throat at the same time, he saw the pin lying across the pharynx just behind the tonsils. All these cases show how little the mere history of a case is to be depended on, one way or the other. The careful examination of the throat by means of well-directed light is of the utmost importance. And no matter how good the light may be in which the throat is examined, if the examining physician or surgeon has no practical knowledge of the throat, the chances are he will fail in his search. A number of first-rate authorities recommend examining the throat and its different localities by means of a sound. And the use of the finger is also recommended. What has been said in reference to good light and visual examination holds good for the tactus eruditus. Dr. Atlee, who has just been quoted, confirms this by writing: "I heard even Nélaton say that in a certain case, after pushing the finger deeply into the pharynx and feeling a small resisting body, he made several attempts to seize it with a forceps before discovering it to be the great horn of the hyoid bone." There are a number of other points in the throat which the unknowing touch might mistake for a foreign body. Roe quotes Cohen as saying that the posterior faucial pillar-its border-might be mistaken for a fish bone. In searching for foreign bodies, when they can not be seen after careful visual inspection, the naso-pharynx may be explored by the finger; and, when possible, a rhinoscopic and post-rhinoscopic examination should be made. The foreign body may have been swallowed and then vomited, and so been forced into the naso-pharynx or into the nose. Or it may have been worked into the post-nasal space by spasmodic efforts on the part of the pharynx to get rid of it. Moreover, especially in the case of fish bones, more than one may be present; and concerning this possibility Sir M. Mackenzie (7) relates the following instructive instance which occurred in his own experience: "An eminent Glasgow surgeon consulted me on account of a fish bone which had become lodged in his throat three or four months previously. I succeeded in removing a fish bone from the lower part of the pharynx. I told him 'he might feel the sensation for a day or two, but there could be nothing more in the throat.' Two days afterward the gentleman returned, saying that there was another bone near the site of the one I had removed, and making an examination I found that his sensations were accurate, and that a second bone was lodged in the throat at the spot indicated. The removal of the bone removed all unpleasant sensations. Between the removal of the first and the second bone no fish had been eaten." In my five cases-the reports of which will now be given-the diagnoses were readily made by means of reflected light and sight. In only one case was it necessary to use the laryngeal mirror; but the laryngeal and post-nasal mirrors were used in all cases. Three of the patients were males and two females. None of them exhibited any physical abnorm-

ity in the mouth, fauces, pharynx, or larynx, nor were any of them bolters of food.

Case I. Fish Bone in Right Tousil Six Years—the Cause of Recurrent Tonsillitis, etc.—George M., aged thirty years, came under my care for follicular amygdalitis. Had many attacks during recent years. Complained that the right tonsil always pained him more or less. The right tonsil was larger than the left, and cheesy concretions in the lacunæ more marked. In cleaning away the cheesy masses from the right tonsil the blunt hook rasped against a hard substance which was supposed to be a calculus. Finally this rough and hard substance was removed from about the center of the tonsil and proved to be a short, thick piece of fish bone about two fifths of an inch long. The patient stated the bone must have been lodged in the tonsil six years. He had consulted a doctor in Scotland on account of pain in the throat after having eaten fish six years ago. It is now (1894) four years since the bone was removed, and there has been no recurrence of amygdalitis.

CASE II.—A girl, aged sixteen years, while eating fish suddenly felt a severe pain in the throat, and, the pain continuing, she sought medical aid. A fish bone an inch and a half long was taken from the right tonsil. The bone had penetrated the upper back portion of the tonsil from above and behind, allowing the free end to prod the soft palate. The bone stuck in the tonsil half an inch; a slight amount of bleeding followed its removal, and with the bone all pain disappeared.

Case III.—A strong, healthy woman while eating fish was suddenly taken with severe spasmodic coughing and vomiting. I was called to see this woman in great haste. In this case a long, slender fish bone had penetrated the posterior faucial pillar (left), the longer and thinner end swinging against the posterior pharyngeal wall, the other thicker end pressing now against the tonsil, now against the base of the tongue. Every time the woman attempted to talk or swallow an attack of coughing and vomiting ensued, and to such an extent as to make her turn blue in the face. The bone was about an inch and three quarters long. It was easily removed with an ordinary dressing forceps, and with its removal the cough and vomiting ceased.

Case IV.—A boy, aged eight years, was suddenly taken with pain in the throat while eating fish, and in such a way that he could neither swallow nor cry without aggravating the pain. This fish bone was fixed in the left lateral wall of the pharynx by one end; the other penetrated the left lateral and middle glossoepiglottic folds. In removing this bone it was necessary to push it toward the median line of the throat to free it from the lateral pharyngeal wall, and then it was easily pulled out. This was done with a long dressing forceps, the base of the tongue being depressed while the tongue was pulled out by its tip. Complete relief followed the removal of the bone and no bad results followed.

Case V is the dispensary case already alluded to, and was also examined by my colleague, Dr. George T. Jackson. In this case the bone was very firmly fixed in the right aryepiglottic ligament. About a sixth or an eighth of an inch of it protruded into the pharynx. For want of a good instrument I failed to remove it. The cannular (laryngeal) forceps that was used let go its hold when traction was made. What subsequently became of the bone and the patient I do not know.

Since these fish bones were removed from their throats, these people have eaten fish often without a recurrence of the accidents for which they were treated. They had often eaten fish before that time with impunity. In view of some of the notions taught concerning the lodgment of fish bones in the throat these facts are important.

II. Reasons for Lodgment or Fixation.—The cases just narrated seemed to me worth recording, and as being a not uninstructive addition to the many already recorded by a number of laryngologists and other physicians and surgeons. While studying cases of this kind—where fish bones, pins, needles, etc., have become lodged or fixed in the pharynx or throat—ideas are apt to suggest themselves that will not harmonize with the teachings often found in laryngological literature respecting the reasons given for accounting for the impaction of foreign bodies in the throat. Besides, such cases are involuntary experiments which illustrate some of the phases of mastication, and which have some influence in deciding the correctness of any theory of deglutition.

George Henry Lewes defines a scientific explanation as being the discovery of those intermediate facts not obvious which link together the obvious phenomena. Now, if we go to our laryngological treatises and text-books, we will look in vain for any scientific explanation as to why these foreign bodies became lodged in the particular localities of the throat where they are found. Take, for instance, Dr. John O. Roe's excellent résumé of the literature of foreign bodies in the throat, and what do we find? In the first place, we are made to infer that the pharynx is a very imperfect organ, since we are told that the natural irregularities of the pharynx tend to the arrest of the different substances that must pass through it in order to reach the stomach, etc. Other writers tell us a similar story. Such is the primary alleged fact. Then we are told that the particular location in or at which the foreign body is caught depends on the anatomical structure of the locality and on the shape, size, and consistence of the foreign body. Thin pointed bodies, it is said, are apter to stick into or become lodged between the pillars of the fauces and tonsils, or in the glosso-epiglottic folds; although, it is further remarked, they may be arrested in any portion of the pharynx. All these assertions are obvious, but they explain nothing, and remain to be explained. When we are told that pathological conditions influence the deposition and fixation of foreign bodies, we are nearing an explanation. But to be told that bad teeth, inflammatory diseases of the mouth, syphilitic local processes, growths in and around the throat, spasms and palsies, etc., are causes of deposition and fixation of foreign bodies in the throat, a scientific explanation is not given us by so doing. This is but indicating some of the conditions favoring such accidents, important of course, but not essential. The same holds true for personal carelessness, hurried eating, etc. Looking into the large number of cases reported by many medical men, we do not find the conclusion forced on us that careless or reckless people, or those who bolt their food, are those particularly afflicted with foreign bodies in the throat. I knew a dressmaker who often went to bed with dozens of pins in her mouth (as she expressed it), and who always awoke in the morning without having got any of them fixed in her throat. She, in a long life, was never bothered by any pin or needle getting into her throat. I

know a half dozen carpet-layers and upholsterers, whose work obliges them to keep their mouths full of tacks for hours at a time, and neither are they bothered by tacks getting into their throats and becoming fixed there. Why? Just because the mouth, fauces, and pharynx are the perfect, exact, and wonderful organs they are. In this connection it may not be uninteresting to recall Ombani's experiments, with twelve young sucking animals (twelve kittens and two rabbits). Ombani forced these animals to swallow a hundred and twenty-seven needles and pins. The number swallowed by each animal varied from one to fiftyeight. Deglutition took place with ease, provided the needles or pins were placed on the tongue longitudinally and the mouth was kept shut. A hundred and ten needles passed away through the anus, one needle was found in the rectum above the sphincter, one transfixed the rectum, one was stuck fast in the walls of the stomach, and two were found in the appendix or cæcum. Three animals, after they had been made to swallow needles, were given emetics. Two of these animals vomited needles. In all three, needles were found transfixing the walls of the stomach. Such is quite a good showing for an apparatus with a bad reputation.

If we turn to anatomists and physiologists for an answer to the question, Why are fish bones, needles, and such similar foreign bodies found caught at or in the particular localities where they are found? they will not give us a direct or ready-made reply. It is easy to say that a foreign body gets where it is found by being swallowed; but so saying is only stating the problem in another way. This problem must take into account two processes: First, mastication, and second, deglutition. Under ordinary or normal conditions the tongue, cheeks, and teeth, in harmony with the jaw muscles and salivary glands, are sensitive to such a degree and their working qualities so well arranged and managed that the bolus is not transferred to the throat until it is properly prepared for propulsion downward. For mastication as well as for deglutition the tongue is the chief active factor. Taking physiologists together, we do not find them unanimous regarding all the details concerning the mechanism of deglutition. Whichever view be adopted, it does not seem irrational to assume that the tongue, after doing its share in the work of mastication and forming the bolus, gives the bolus a twist as it shoves or propels it down through the pharynx. It does not seem difficult, from its complicated anatomy and the multiplicity of its many possible movements, to suppose this to be the case-that is, to initiate the deglutitory movement with a screw-like motion or gyration, a movement which it would seem must facilitate the passage of the bolus, and which at the same time would lend force and expedition to the other deglutitory process acting on the down-speeding bolus. The conformation of the pharynx during deglutition would seem to favor this view. The pharynx is funnel-shaped; and we know that fluid forced down a funnel gyrates. Then, too, it may be asked, May not that force, or one similar to what gunners call "windage," but conformant to the organic conditions of the pharynx, etc., be at work here and aid in the gyratory movement of the bolus through the pharynx? We all know that it is easier to force a

probe through a solid by pushing it with a rotatory movement; and we also know that it is easier to pull a plug from its place of fixture by adding rotation to the pulling force. These instances are, of course, only analogies, and prove nothing positively; but they indicate possibilities. We all know by experience that we talk faster than the clock ticks, and Kronecker and Meltzer have, by means of ingenious mechanical contrivances, demonstrated that we swallow much more quickly than we talk-that is, we swallow at the rate of about an inch in a hundredth of a second. Deglutition is in the dark in more senses than one. And, besides, it is no easy matter to observe all that occurs, and how it all occurs, in so complicated and complex a process as deglutition is-everything taking place with almost "lightning rapidity." If, however, the gyrating or screw-like movement of the "shooting" bolus could be proved experimentally—that is, if this idea could be made a fact—the explanation of the fixation and impaction of foreign bodies like fish bones, etc., in the throat could be more easily explained than can be done by assuming that the food goes down in a straight line. It seems easier to conceive of a long fish bone stitching itself into the posterior faucial pillar-as in the case of the woman reported above-than by force thrust in a straight and undeviating line. A rotating bolus, it seems to me, would much more readily free itself from any particle in it that had fixed itself at any point in the tract it is forced to travel. These foreign bodies-fish bones, pins, needles, etc. -vary in length, and lie at different and varying angles to the long or descending axis of the bolus, during both mastication and deglutition. During the rapid process of deglutition the shape of the bolus is necessarily changed by the forces acting on it. The fauces being the first station where these changes occur, the greater number of these foreign bodies are deposited here, especially in the tonsils (Brodie, Bosworth, Knight, and others). The deglutitory forces continuing to act, the bolus is continually changing its form, and the contained fish bones, etc., are necessarily shifting their places and the angles at which they lie to the long axis of the bolus; and the ceaseless transformation of the bolus and its contents being a matter of time and place, relatively considered, any point in the pharynx or œsophagus may be penetrated by the foreign body that may happen to be in the bolus. But the original position in the bolus of a pin, needle, or fish bone immediately after mastication and as deglutition begins decides the fate of these foreign bodies, and hardly so any of the natural or normal irregularities of the fauces and pharynx as seen in a state of rest with the mouth open. Foreign bodies, such as we are considering, lying parallel with the long axis of the bolus will probably reach the stomach with the bolus; and once more, in the way of corroborative evidence, I may direct attention to Ombani's experiments. But if these foreign bodies are at an angle to the long axis of the bolus, the chances are that they may be held up somewhere in the throat, unless the forces acting on the bolus shift them parallel, or nearly so, to the long axis of the line of travel. According to the experimental results of Falk, Kronecker, and Meltzer, the bolus is thrown into the cardia

before the muscles of the pharynx contract, and within a tenth of a second as to time. However, immediately after the bolus has passed through the throat the middle and inferior constrictors of the pharynx contract in a quick, graded, and regular order, and sweep down into the œsophagus the particles of food which detached themselves from the bolus and remained clinging to the pharyngeal walls as the bolus was hurried or shot downward. These observations, it seems to me, can be plausibly utilized in explaining how fish bones become fixed in the throat; and, moreover, they do not stand in the way of the opinions bearing on this question as outlined, nor do they contradict them in any way. For instance, the mode of impaction of the fish bone in the Northern Dispensary case may be explained thus: Possibly the bone was shifting its position all the while the bolus was being whirled down the throat until its point struck the arytæno-epiglottic fold; the onward whirl of the bolus stitched in the bone to a certain distance, tore itself loose, and whirled onward; and immediately this was done the succeeding contraction of the pharvngeal constrictors pushed the bone still farther in. These possibilities are not excluded by hypothetical assumptions I have endeavored to explain, and the results of the Kronecker-Meltzer experiments. It must not be forgotten that these phenomena take place within the fraction of a second-primarily. Of course, subsequent pharyngeal contractions, tongue movements, the rising of the darynx, etc., would tend to drive an already fixed foreign body, like a fish bone or a pin, still deeper.

Stuart and McCormick came to the conclusion, after observing the throat through a hole in the side of the neck of a man,\* that the epiglottis, at least so much of it as could be seen, does not move or bend over to cover the glottis during deglutition. When this patient was given an oyster to swallow they could see how it glided over the laryngeal surface of the epiglottis on its way downward. The oyster was received within the hollow of the tip of the epiglottis, along which they saw it glide for a certain distance. When oysters were swallowed, twice in three times they were expelled from the pharynx through the surgical hole in the side of the neck. This seems to prove that the epiglottis is not the guide of the food downward immediately after it leaves the base of the tongue; and, furthermore, that the pharynx in a normal state exerts an equalizing pressure on the descent of the bolus, if not (as Kronecker and Meltzer believe they have demonstrated) an active direct propulsive action.

<sup>\*</sup> This man had undergone four operations for the removal of epithelioma, and the hole in the neck was left after the following parts had been cut away: The parotid gland, the ramus of the jaw, a piece of the hypoglossal nerve, the pes anserinus of the facial nerve, portions of the internal, external, and common carotids, the greater part of the great horn of the hyoid bone, the posterior belly of the digastric muscle, the faucial pillars and faucial tonsil—all on one side.

<sup>†</sup> The following observations are so interesting in themselves, and, I believe, in a measure assist in better understanding the mechanism of deglutition, that they may profitably be repeated here: Dr. Stuart had a meal with this patient, and he writes as follows (the patient had devised a pad for keeping the hole in the side of the neck closed): "The patient had no apparent difficulty with his food, whether liquid

Magendie, more than eighty years ago, demonstrated that the epiglottis is not necessary to successful swallowing. Since his time physiological experimentation and clinical observation have made this a fact and truism. Schäffer (11), (Bremen), has described a number of cases of deformed epiglottis, and among the symptoms which the deformities gave rise to were deglutitory difficulties. The epiglottides in these cases were large and irregular in shape, and probably in a measure on these accounts interfered with the deglutatory phenomena. Stuart and Mc-Cormick, in their article already quoted from, state that the epiglottis in their case stood still against the base of the tongue during deglutition. Michel (12) speaks of a primary ædematous affection of the anterior aspect of the epiglottis which occurs when the pharyngeal condition might lead one to overlook it. He calls it angina epiglottica anterior, and says it presents a swelling of about the size of a hazelnut and more or less reddish-gray in color. In these cases the fossæ glosso-epiglotticæ were almost unrecognizable. This condition of the epiglottis gave rise to painful deglutition, and no doubt an abnormal position of the epiglottis, making it impossible to cover the glottis during deglutition, as well as standing up against the base of the tongue, as Stuart and McCormick have seen that it does. Wagner, of this city, has removed the epiglottis in toto by a subhvoidean operation, and no deglutitory difficulties ensued. Pathological instances might easily be multiplied to prove, what physiologists have demonstrated over and over again, that the epiglottis is an indifferent organ in so far as deglutition is concerned. Some phonatory functions have been claimed for it. It is in the pharynx during deglutition, and so it must be accounted for; and if foreign bodies get behind it (as in Schäffer's case, a fish bone in the left interglosso-epiglottic space) or alongside of it, or transfixed through the glosso-epiglottic folds, any theory of deglutition must account for such accidents, and in doing so the deglutitory theory gives an account of itself and in so far justifies its validity. In view of the observations made by Stuart and McCormick, and the physiological and pathological demonstrations referred to and mentioned, the shutter function of the epiglottis must be abandoned.

When a foreign body has fallen in front of the epiglottis—the anatomical conditions being normal—into either of the vallecules, it possibly became detached from the bolus very early in the series of deglutitory phenomena, or slipped along too late and missed being acted on as fully as the bolus was acted on, and consequently it slipped

or solid. When he had his mouthful masticated and ready for swallowing, he laid his hand upon the pad, to more securely close the opening, just as he always does when he speaks, and then he swallowed quite well. His only common inconvenience is that sometimes in swallowing liquids a little remains behind, and when this is swallowed it is apt to get into 'the wrong throat.' This is easily understood when we remember (1) the imperfectly contractile channels through which the liquids must pass; (2) one side of the lower jaw being absent, the elevators of the hyoid bone can hardly act so efficiently as normally; (3) the hypoglossal and part of the facial nerve of one side being wanting. . . . Occasionally a little piece of solid food gets against the pad; then it may annoy him in the same way as the liquids referred to, but this does not very often happen."

down between the tongue and epiglottis. Or the fish bone occupies a favorable position on the outside of the bolus—it attaches itself to the pharyngeal wall and, its point swinging into the glosso-epiglottic fold, the subsequent secondary pharyngeal contraction and after-contractions stitch it in to the limits of force and space. Of course, in all possible instances, one can vary the theorization of fish-bone impaction at will—but only so within the limits of the forces named.

I have not alluded to nor taken into account all the forces at work during deglutition. That was not the object of this paper. I believe, however, that what has been said from an anatomical, physiological, pathological, and experimental point of view allows the following conclusions to be drawn:

- The reasons for the impaction of foreign bodies, such as fish bones, needles, pins, and the like, are not to be sought for in the pharynx primarily.
- That, under normal conditions, the tongue, fauces, and pharynx, in so far as deglutition is concerned, are perfect organs, looked at as a mechanico-physiological apparatus.
- 3. The primary and chief cause of fish bones, needles, etc., being caught or entangled in the throat must be looked for in the bolus itself—the position of the fish bone or needle in the bolus, whether lying deep or on the surface, the angle the fish bone or pin occupies to the long axis of the bolus, and, besides, the varying and various forces that act on the bolus as it is forced toward the stomach.
- 4. Possibly the bolus leaves the tongue and descends the pharynx with a twist or screw-like movement.
- 5. The Falk-Kronecker-Meltzer conception of deglutition, based on experimental results, may be utilized in explaining how fish bones become impacted in the throat and these experimental results do not exclude the element of gyration as one of the forces that impel the onwardshooting bolus.
- 6. The epiglottis is an indifferent organ in so far as deglutition is concerned—also for foreign bodies.\*

<sup>\*</sup> While studying at some of the throat clinics in Germany during 1880 and 1881, I often heard one of the deglutitory functions of the epiglottis explained as being a sort of guard standing firmly against the current of foods and liquids as it came down from the tongue. It was supposed that the epiglottis divided this current and caused the foods and liquids to course laterally around the larynx into the esophagus, which stood open to receive them. Heavier or large morsels, which would not divide, toppled over the epiglottis into the œsophagus. This theory of deglutition always seemed to me grotesque and inadequate. However, the most recent German book on the science and art of laryngology, very well written, as was to be expected, by Professor Dr. Moritz Schmidt, Frankfort a. M., still clings to this theory. If that were all, this note would not have been written; but Professor Schmidt also asserts in this same very good book that small, sharp-pointed foreign bodies are caught up in the epiglottis quite often, and that they occasionally penetrate it (page 471). These statements are made in a general way, and no specific instances are narrated, nor are any references given of such. Has he seen such instances in his own extensive practice? If foreign bodies do frequently fix themselves into the epiglottis and occasionally penetrate it, two good arguments are always close at hand to defend the deglutitory guard, etc., theory of the epiglottis (Schmidt, pages 44, 45). But, unfortunately, I can find neither

instance nor any authority to corroborate the assertions made by Professor Schmidt. I have looked in vain for such instances in the indexes of the following special publications: (1) Annales des mal. des l'oreilles et du larynx, from 1875 to 1893; (2) Arch. de laryngologie et de rhinologie, 1887 to 1892; (3) Internationales Centralblätt für Laryngologie, etc., nine vols.; (4) Monatsschrift für Ohrenheilkunde sowie f. Kehlkopf-Nasenvachenkrankheiten; (5) the Journal of Laryngology, etc., 1887 to 1893; (6) Elsberg's Arch. of Laryngology, four vols. And neither do any of the following standard writers mention, even in a general way, the epiglottis as a seat for sharp-pointed foreign bodies: Massei, Knight, Bosworth, Schuh, Jurasz, Schrötter, Mackenzie, McBride, Rethi, Rosenberg, Rae, Bresgen. In view of all this evidence against the assertions of even so genial a man as Professor Schmidt is known to be. I am sure this conclusion—the epiglottis is indifferent to foreign bodies, small and sharp-pointed-may fairly be allowed to stand.

#### REPORT OF

#### FIFTY-SEVEN CASES OF INSANITY

7. Sir M. Mackenzie, M. D., etc. A Manual of Diseases of OCCURRING IN SIX YEARS AMONG SILK-MILL EMPLOYEES IN A MANUFACTURING CITY IN NEW JERSEY.

By WILLIAM PHILIP SPRATLING, M.D.,

NEW YORK,

FORMERLY FIRST ASSISTANT PHYSICIAN,

NEW JERSEY STATE HOSPITAL FOR THE INSANE AT MORRIS PLAINS;

MEMBER OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

AND OF THE HARLEM MEDICAL ASSOCIATION OF THE CITY OF NEW YORK.

These cases are reported for two reasons: First, because so great a number of cases of insanity occurring in so short a period of time, among persons following the same vocation in a city having a population of less than a hundred thousand souls, is most unusual.

Second, because a majority of the cases here reported clearly demonstrate the causal relationship between prolonged and excessive overtax of mind and body and the production of insanity.

These cases were committed for treatment to the New Jersey State Hospital for the Insane at Morris Plains, within a period of six years, beginning January 1, 1887, and ending December 31, 1893. Many cases were admitted prior to January 1, 1887, but as most of them were transfers from other institutions, and chronic cases of long standing, they have not been taken into account.

In the following table, the age, sex, alleged cause of insanity, heredity, form of insanity on admission, duration of the disease, and the result are given:

TABLE I.

Case number.	Age.	Sex,	Alleged cause.	Heredity.	Form of mental disease.	Duration of treatment.	Result.
		-	-	37	26.2 .2 2	0	Dementia, death.

Table II.—Showing Age when admitted.

	Male.	Female.
Up to 15 years	1	
15 to 20 years	1	6
20 to 25 years	5	6
25 to 30 years	5	7
30 to 40 years	10	4
10 to 50 years	5	4
50 years and over	3	

Table III.—Showing alleged Cause of Mental Disease.

Overwork	29
Overwork and heredity	4
Alcohol	4
Epilepsy	4
Menopause	. 1
Unknown	13

By adding the four due to overwork and heredity to those chargeable solely to overwork, we have a grand total of thirty-three, or fifty-seven per cent. of the entire number, due to this cause alone. This percentage might very properly be further increased by adding to the total a certain proportion, at least a half, of the thirteen cases whose cause is put down as being unknown. This would increase the percentage of cases due to mental and physical stress to seventy per cent.

A history of hereditary taint was ascertained in four cases only.

Case No. 13, mother insane.

Case No. 21, maternal grandmother insane.

Case No. 28, mother insane.

Case No. 39, mother and paternal uncle insane.

Table IV.—Showing Form of Mental Disease at Time of Admission to Hospital.

Mania, acute	18
Mania, acute delirious	1
Mania, chronic	4
Melancholia, acute	22
Melancholia, chronic	4
Dementia, epileptic	4
Dementia, primary	3
Paranoia	

By adding together the acute diseases—namely, acute mania, acute delirious mania, acute melancholia, and primary dementia—we have a total of forty-five, which constitutes a fraction less than seventy-nine per cent. of the entire number.

A greater number suffered from acute melaucholia than from any other single type of mental disease, thirty-eight per cent. of the entire number having this form.

Regarding the duration of the disease, twenty-eight were under treatment less than a year, ten between one and two years, and nineteen two years and over.

Of the twenty-eight who were, and up to December 31, 1893, had been under treatment less than a year, 12 were discharged as recovered, 2 were discharged as improved, 4 were discharged as unimproved, 5 died, and 5, on December 31, 1893, were still in hospital.

Of the remaining 29, under treatment a year and over, 2 were discharged as recovered, 3 were discharged as improved, 2 were discharged as unimproved, 1 died; leaving 21, on December 31, 1893, still in hospital under treatment.

A summary of the result in the entire number of 57

cases would be as follows: 14 cured, 5 improved, 6 unimproved, 6 died, 26 remaining in hospital under treatment as chronic and incurable.

We recognize in the figures the fact that the type of insanity in these cases was particularly severe. Only 19 out of the 57 got well, or showed any improvement, while 6 of the remaining 38 died, leaving 32 cases as incurable.

In looking for the causes of these cases, our task is not difficult.

Mercier, writing upon the causes of insanity, says: "Insanity is, in mathematical terms, a function of two variables. That is to say, there are two factors, and only two, in its causation, and these factors are complementary. Both enter into every case of insanity, and the stronger the influence of one factor, the less of the other factor is needed to produce the result. These factors are, in brief, 'heredity and stress.' The word 'stress' is used in this connection in its broadest sense. It includes violence to body as well as to mind. Stress means more than strain, which is commonly employed to designate mental tension."

Stress, direct, continuous, and powerful, was the sole cause in a majority of these cases. It was applied in different ways: Long hours daily spent in managing complex and delicate machinery; one person sometimes doing the work of two or more in order to increase his earnings; insufficient mental relaxation and rest; insufficient outdoor exercise; the accuracy and complexity of manual motion, and mental application constantly required; the vitiated atmosphere and poor food are the prime factors in the production of so many cases of insanity among this class of people.

I recall the case of one young woman twenty-four years of age, bright, vigorous, and industrious, who, after doing the work of three persons in one of these mills for some months, in order to support a widowed mother and several brothers and sisters, broke down with paresis, and was placed in an asylum, where she died in less than a year after.

The number of cases of insanity that come! from these mills is increasing annually.

70 West Eighty eighth Street.

# THE PRACTICAL WORKINGS OF THE NEW LAWS FOR THE STATE CARE OF THE INSANE.

By CARLOS F. MACDONALD, M. D.,

PRESIDENT OF THE NEW YORK STATE COMMISSION IN LUNACY;
PROFESSOR OF MENTAL DISEASES IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE;
LATE LECTURER ON INSANITY IN THE ALBANY MEDICAL COLLEGE.

(Continued from page 557.)

Among the more important improvements and reforms which have been established and carried into successful practice under the new laws may be mentioned the following:

1. The adoption, July 1, 1890, of a new and improved form of medical certificate in lunacy, designed, on the one hand, to facilitate the commitment of insane persons to in-

stitutions, and, on the other, to surround the liberty of the individual with better safeguards against carelessness and wrongful intent than had theretofore existed, while at the same time permitting of efficiency and celerity of operation, and also insuring a much greater amount of information for the medical officers of the hospitals than was possible under the method which it supplanted. In order to secure uniformity, all blank commitments are now furnished by the commission, the blanks being printed on stereotyped plates, which are the property of the State. These printed blanks are used for copies as well as originals, and may be obtained free of cost on application to county clerks, superintendents of hospitals, asylums, homes, or retreats, and superintendents of the poor. Certified copies of all commitments are required to be filed in the office of the commission within ten days after the patient's admission to the hospital, where they are carefully scrutinized with reference to correctness of form, sufficiency as to facts indicating insanity, and also as to the qualifications of the certifying physicians. This enables the commission to detect and promptly correct any irregularity, whether intentional or otherwise, in the commitment of the insane. As showing the extent to which error has been eliminated by the adoption of this form, it may be stated that the commission has now to reject by reason of defect as to form, insufficiency of facts, or lack of legal qualifications of examining physicians, less than a half of one per cent. of all the medical certificates received.

- A registration in the office of the commission of all qualified medical examiners in lunacy in the State, whereby the commission is enabled to at once determine on receipt of a lunacy certificate if the examiners signing the same are legally qualified to perform these services.
- 3. A complete registration in the office of the commission of all persons held in custody as insane, whether in public or private institutions, with minute data as to the name, age, sex, nativity, occupation, civil condition, date of commitment, names of the signers of the medical certificate and of the judge approving the certificate, date of admission, whether brought from home or an institution, by whom brought, and the insane person's physical condition. The records also show the date of discharge of each patient, and whether recovered, improved, or unimproved, and to whose care discharged; if transferred, for what cause and to what institution, and, if dead, the date and cause of deaththus enabling the commission to determine accurately at all times the number, condition, and increase of the insane in the State and to furnish for proper use this and other valuable information which it was impossible to obtain before the establishment of this bureau of registration.
- 4. The adoption for all the hospitals and asylums, public and private, of a uniform system of statistical returns, thus enabling any one who may desire to do so to make intelligent comparisons as to the results in the various institutions in the State.
- 5. The establishment of a uniform system of medical records, including case books, prescription records, records of admissions and discharges, daily reports, etc., and the requirement that entries showing the condition and progress of each case shall be made in the case-book records at

least once in each month during the first year and at least once in every three months thereafter.

- 6. The establishment of a uniform system of receipts and expenditures in all the State hospitals, thus providing for intelligent comparison as to the expenses of these institutions. Formerly each hospital had its own system of records and accounts, each being different from that of any other hospital.
- 7. A provision for the transfer of patients from one institution to another, on the order of the commission, whenever, for any sufficient reason, it may be deemed desirable to do so.
- 8. A regulation providing for the admission of private patients to State hospitals from any part of the State without restriction as to district, at a maximum rate not to exceed ten dollars per week, at the same time protecting the rights of public patients and of such as can pay only small sums per week, by requiring that no private patient in any State hospital shall be permitted to occupy more than one room for his or her personal use, or to command, except for medical reasons, the exclusive services of an attendant, and that there shall be no distinction between public and private patients as regards the scale of care and accommodations furnished them.
- 9. An effort, which has been fairly successful, to induce or compel the friends or relatives of patients who are able and legally liable therefor to reimburse the State for the support of such patients. It was found that a large number of persons who were able and liable had heretofore evaded this obligation.
- 10. The adoption of regulations governing the transfer of patients from their homes or from poorhouses to State hospitals, requiring that such patients before being sent to the asylum shall be in a state of bodily cleanliness and suitably and comfortably clad.
- 11. Providing that the hospitals shall send a trained attendant to bring patients thereto, and that in all cases of female patients there shall be provided a female attendant. This system insures a greater degree of comfort and decency in the removal of patients to the hospitals, and it has thus far shown a very marked reduction in the cost of such transfer as compared with the old system of transfer by county superintendents of the poor.
- 12. Provision for the paroling of patients who are not regarded as homicidal, suicidal, or otherwise dangerous for a period of not more than thirty days, during any portion of which they may be returned to the hospital without new process of commitment, or they may be permanently discharged, thus affording patients whose condition is such as to warrant it an opportunity to visit their homes or to go out on trial before final discharge.
- 13. A regulation requiring that all patients on admission to a hospital or asylum for the insane, whether public or private, shall be immediately informed of the nature of the institution and the fact that they are detained there under legal commitment. The adoption of this regulation was suggested by the fact that patients frequently complained to the commissioners that they had been decoyed into the institution and only accidentally discovered that they were

detained in a lunatic asylum. Several instances were found where the fact of commitment and detention had apparently been deliberately concealed from the patient until it was made known to him by the visiting commissioners. The deception of insane persons in this manner is deprecated by all who have had experience in dealing with this class, it being recognized as an important element in the treatment of the insane that no deception should be practiced.

- 14. A division of the State into hospital districts with reference to the number of insane in each district and the extent of accommodations in the hospital located therein. This provision of the State Care Act is sufficiently elastic to admit of a change in the limits of any district whenever it shall be deemed necessary to more conveniently care for the insane in the various hospitals, or to better accommodate the convenience of any particular locality.
- 15. A change in the legal title of the State institutions from "asylums" to "hospitals," and a reorganization of those State institutions \* which were formerly asylums for the chronic pauper insane upon a hospital basis, thus establishing the hospital idea for all.
- 16. A provision for the admission of public patients to a State hospital beyond the limits of the district in which they reside whenever, for any sufficient reason, they or their friends may so desire. This is especially designed to provide for such patients as may desire treatment in a homœopathic hospital, or in case of patients residing in the homœopathic hospital district who may desire other than homœopathic treatment.
- 17. An order for the regulation of the correspondence of the insane, providing that each patient be permitted to write to some relative or friend once in two weeks and oftener if necessary, in the discretion of the medical superintendent, and, if patients themselves are unable for any cause to write, the medical superintendent must delegate some proper person to write for them at suitable intervals if they so desire; all letters to be forwarded at once to destination unless they are profane, obscene, or too illegible or incoherent to be understood, and the postage must be furnished by the institution if the relatives or friends are unable to provide the same. All letters detained because of obscenity, profanity, or for any other reason must be forwarded at once to the office of the commission with the reasons for detention indorsed thereon, All letters addressed to the Governor, attorney general, judges of courts of record, district attorneys, or to the State Commissioners in Lunacy must be forwarded at once without examination. This order is designed to afford patients who regard themselves as illegally detained or improperly treated an opportunity to communicate with their friends or with any official in the State who would have jurisdiction in a lunacy case.
- 18. The investigation by the commission of hundreds of complaints of illegal detention or abuse on the part of patients, every patient who requests it, or whose friends may request it, being granted a hearing apart from any officer of the hospital, if the patient so desires.

<sup>\*</sup> Willard and Binghamton.

19. The adoption of an order requiring the superintendent or physician in charge of each institution for the care and treatment of the insane not to permit the service of any legal process whatever upon an insane patient, except upon the order of a judge of a court of record, which order shall show that the judge had knowledge of the fact that the person upon whom the process is sought to be served was at the date of the order an inmate of such institution; that no insane person be permitted to sign any bill, check, draft, or other evidence of indebtedness, or to execute any deed or mortgage, or other legal conveyance, except upon the order of a judge of a court of record which shows that the judge had notice of the fact that the person whose signature is sought to be obtained was at the date of the order an inmate of an institution for the insane; also that the substance of the order and the proceedings had thereunder must be entered in the history of the patient in the asylum case book, and a copy of the same forwarded to the committee of the person and property of the patient, if there be one, or, if there be no committee, then to the nearest known relative or next friend of the patient. This order is designed to protect the interests of the insane against designing persons, and especially to prohibit the wrongful service of papers on lunatics in divorce proceedings.

20. A regulation for the admission of voluntary patients to such of the private institutions for the insane as are conducted on the so-called "family plan." For legal reasons, which are regarded as sufficient, the admission of voluntary patients to public hospitals or to incorporated private hospitals is not permissible.

- 21. The adoption of an order revoking the licenses of all private asylums conducted by laymen, and restricting the licensing of private asylums, homes, and retreats to reputable physicians of experience in the care and treatment of the insane.
- 22. The adoption of a regulation requiring all hospitals and asylums for the insane, both public and private, to provide a liberal amount of fire protection, the extent and variety of such means of fire protection being determined by the commission according to the location, extent, and arrangement of the institution.
- 23. The substitution, in all cases, of wire beds, hair mattresses, and woolen blankets for straw beds and cotton quilts, which were formerly more or less in use in many of the institutions.
- 24. An order prohibiting the purchase of adulterated food supplies of any kind for use in State hospitals; also for the purchase, wherever necessary, of a generally better quality of staple articles of food supply; also a better grade of clothing, and better quality and increased amount of furniture, in the way of carpets, rugs, easy-chairs, pictures, etc.; a large increase in the amount of reading matter supplied to patients, and a marked extension of the facilities for amusements and diversion and for the industrial occupation of patients; also for an increased ratio of attendants to patients, the establishment of attendants' homes at several of the hospitals, and a better rate of compensation to attendants; also the introduction of women

attendants in the men's convalescent wards and in the ward dining-rooms for men; the introduction of spray baths, especially for the bathing of filthy patients; the abolition of airing courts or inclosed exercise yards, thus affording patients a larger degree of freedom than heretofore; the complete abolition of all mechanical restraint in the management of the insane, except in one or two hospitals where there is still a tendency to cling to old methods which are now nearly everywhere regarded as obsolete; the establishment of an efficient system of night service of attendants in all the public hospitals for the insane; the general adoption in the hospitals, both public and private, of a uniform dress for attendants' wear; the establishment of infirmary or hospital wards, under the charge of a hospital attendant skilled in nursing the sick, for patients who are sufficiently ill to require treatment in bed.

25. The removal of patients to other States and countries, in cases where it can be determined that the patient is a non-resident of the State. By this means the number of public patients supported by the State has been materially lessened.

26. A successful effort to induce the authorities of New York city to set apart specific appropriations for the benefit of the insane in the institutions under the Department of Charities and Corrections, and to prohibit the use of these moneys for any other purpose. This has resulted in a general improvement of the standard of care of the insane in the city institutions, and especially in the matter of bedding and in the quality of the food supplies, beef being now supplied in carcass in place of "chucks and necks" as formerly. A better quality of flour has also been secured to the inmates of these institutions.

27. The adoption of an order by the commission providing for the appointment of a general medical superintendent for the Kings County lunatic asylums, who shall have power to make rules and regulations for the government of the asylums, appoint and discharge all employees, regulate the dietary, make ordinary repairs, etc. This order was appealed from by the local board, but the higher courts sustained it, and its effect has been to remove the immediate management of the Kings County asylums from partisan influences which have hitherto been so detrimental to these institutions, and to generally improve the standard of care afforded to their immates.

28. The publication of an official directory of all the hospitals and asylums, licensed private asylums, homes, and retreats for the insane in the State, showing the location and capacity of each institution, how reached, and the name of the superintendent or physician in charge; also, in the case of private institutions, the minimum rate per week charged for maintenance.

29. Provision for the clinical teaching of insanity in hospitals for the insane by the admission to the wards thereof of students of medical colleges situated in their vicinity, as well as of practicing physicians, who may desire the opportunity of clinically studying mental diseases, under such restrictions as the medical superintendent may deem wise and proper, thus enabling, as far as practicable, physicians engaged in general practice, and upon whom the first

care of nearly all cases of insanity necessarily devolves, an opportunity to acquire a practical knowledge of this disease, if they so desire.

30. Provision for the appointment from among recent graduates in medicine of two medical internes in each State hospital, in addition to the regular medical staff, thus providing for a training school for medical officers in these institutions, from which the regular medical staff may be recruited.

31. The abolition of the spoils system in the selection of medical officers of State hospitals through the adoption by the State Civil Service Commission, upon the recommendation of the Commission in Lunacy, of a regulation requiring appointments of all medical officers in State hospitals to be made only after competitive civil-service examination, and raising the standard of requirements for eligibility to such examinations. This has already resulted in the merited promotion of a number of experienced assistant physicians who otherwise would not have obtained promotion save through favoritism.

32. A material increase in the proportion of medical officers to patients in both public and private institutions.

33. The enactment and fulfillment of a law requiring the appointment of a woman physician on the staff of each State hospital, at a fixed salary of twelve hundred dollars per annum.

In connection with this subject it may be stated that the commission has in contemplation the appointment at an early day of a special pathologist, with a completely equipped laboratory, for the prosecution of investigations in neuro-anatomy and neuro physiology and in the study of brain pathology. It is designed to make this department practically a school for the teaching of brain pathology to physicians who may desire to avail themselves of it, and especially to such of the physicians on the staffs of the respective State hospitals as possess an aptitude and desire for such work.

Respecting what has been done in the direction of improvement of the hospitals themselves and for the promotion of the welfare and comfort of their inmates, as a result of the adoption of the policy of State care, a perusal of the annual reports of the State hospitals will show that the condition of these institutions as regards organization, equipment, sanitary condition, fire protection, clothing and furniture, food supplies, discipline, nursing, means of diversion and occupation, and medical service has been steadily progressive, and that the standard of care generally is very much higher than it was five years ago, when the State Commission in Lunacy was created.

These reports not only reflect the improvements which have been wrought at the Binghamton and Willard Hospitals, which formerly cared only for the so called "chronic pauper insane," and maintained a correspondingly low standard of care, and the progress of the Rochester State Hospital, which, prior to 1891, was a county asylum with meager facilities for the care and treatment of its inmates but they substantially outline the present status and condition of all the eight State hospitals.

The superintendent of the Binghamton State Hospital, in his report for 1893, states as follows:

"Analysis of the table showing the causes of death, and comparison with similar tables for preceding years, afford extremely gratifying results. The reduction in the death rate is not only gratifying when computed on the number admitted, but is also highly satisfactory when based on the average daily population, for on this basis, during the past ten years, it has fallen from 11.73 per cent. in 1883 to 6.35 per cent. in 1893. The question naturally arises, To what is this remarkable improvement due? To you who have seen the institution grow from a poorly equipped, crudely furnished, poverty-stricken asylum for the chronic insane into the splendid hospital of to day, supplied with modern sanitary appliances, provided with good food and raiment for its patients, diversified occupation and amusements to engage their hands and minds, and kind nurses to watch over them, the question needs no answer. Improved surroundings, humane care and treatment, freedom from mechanical restraint, and the largest personal liberty consistent with safety, are the agencies through which the change has been accomplished. Up to the year 1890 it was with exceeding difficulty that the bare necessaries of life could be procured for our patients, but when in that year the State Care Bill became a law this hospital, scarcely recognized by its sister institutions, was suddenly galvanized into life, and under the beneficent provisions of that act it received a new impetus which enabled it to rise rapidly to high rank in the State. Under the old law anything was good enough for the broken down, chronic cases it sheltered; under the new law the arbitrary distinction between acute and chronic insanity was legally annihilated, and the doors of the hospital were opened to all for whom admission was sought from the eight counties constituting the district assigned as its bailiwick.\* Of this law the American Journal of Insanity for April, 1890, speaks in the following language: 'The State Care Bill, providing State care for all the dependent insane in the State of New York, became a law April 15, 1890. By signing this bill Governor Hill consummated one of the most signal triumphs ever achieved by humanity in the State of New York. All honor to those good men and women who have labored zealously day in and day out for the past three years to bring about this happy result. In the general rejoicing there will be no caviling as to who is entitled to the lion's share of the credit, though all must recognize the important part played in this great reform by the State Commission in Lunacy.' As was forecast by the Journal's prophetic utterance three years ago, hundreds of patients in this hospital are to-day living testimonials of the humanitarianism of this law."

The report of the trustees of this hospital for 1892 contains the following:

"Since the enactment of Chapter 126 of the Laws of 1890, popularly known as the State Care Act, the character of this institution has gradually undergone a change. The chronic asylum element has been steadily eliminated as

<sup>\*</sup> In these quotations from the hospital reports the Italics are the writer's.

the 'hospital idea' has gained stronger foothold. The wards have taken on a more cheerful aspect, and the patients have become more tractable under the humanizing influence of artistic furniture, pictures, rugs, carpets, curtains, and other draperies, all of which please the eye, cheer the mind, and tend to promote the recovery of the patient. Tablecloths have been introduced in all the dining rooms, and better tableware is generally in use. The steel ceilings provided for by the last Legislature have been erected to the extent of thirty-two thousand feet, and they not only beautify the wards but give assurance of safety against falling masses of plaster, and guarantee material protection against fire. . . . Large numbers of patients have found useful and beneficial occupation on the farm, and have exercised better self-control and enjoyed better health when thus employed than when idle." And again: "The State Commissioners in Lunacy have made frequent visits at the hospital during the year, and have made valuable suggestions regarding its management. It affords us pleasure to state that they have co-operated with the trustees and resident officers to the end that the institution might attain the highest degree of efficiency and that the patients should derive the greatest possible benefit."

In this same report the superintendent says: "Material progress has been made along the lines of hospital administration that now attract the greatest attention-viz., greater personal attention to the insane, more diversified occupation, and greater individual liberty." And again, in referring to the work of the State Commission in Lunacy, Superintendent Wagner says: "I should be derelict in my duty if I failed to make acknowledgment to the State Commission in Lunacy for advice and encouragement in carrying out the details of hospital organization and management. The recommendations of the commission during the past twelve months have been uniformly in the direction of a higher and better service in the hospitals of the State, and their interest has been keenly alive to all questions affecting the welfare of the patients, as has been evidenced by their frequent visits and inspections."

The superintendent of the St. Lawrence State Hospital, in his report for 1892, states as follows: "The service of the hospital is progressively improving, and particularly with respect to the immediate care of patients. Aside from the improvement resulting from experience in the care of the insane, the training of a fair proportion of our nurses and attendants systematically has had a marked influence upon the whole number by the example of their skilled service."

The report of the superintendent \* of the Willard State Hospital for the year 1892 states as follows: "A great deal of new furniture has been purchased and placed upon the wards, and a number of painters, carpenters, and plasterers have been kept busy repairing and beautifying various parts of the institution. The branch, or infirmary for women, has been renovated and decorated throughout, and

it now presents a remarkably cheerful appearance. The lower floor of the main building, consisting of three wards each for men and women, is also in excellent condition. Among the articles of furniture purchased were five pianos, a music box, and a billiard table. Every building in which there are women has now a piano, while the woman's department in the main building has two." And again: "Up to a year ago the normal capacity of the institution was considered to be nineteen hundred and thirty-eight, and, as we then had an average of two thousand and fifty patients, more than a hundred were compelled to sleep upon the floor, or in cots placed nightly in the corridors and removed during the day. But, by building the additions for the new dining rooms and turning the abandoned ones into dormitories, by adding a bed here and there where space would permit, and by finding sleeping apartments off of the wards for several employees who had no ward duties to perform, the capacity has been gradually increased until now twenty-one hundred patients-a thousand men and eleven hundred women—can be comfortably cared for. paradoxical as it may seem, the capacity of the institution has been increased by one hundred and sixty-two beds, although not a single ward has been added to the hospital. This entire increase, which would have cost the State \$89,-100 had a building been erected under the State Care Act at a per capita cost of \$550, has been brought about by an expenditure of about \$11,000 for new dining rooms, and about half of that sum for interior alterations." This report further states that: "The night service in the main building has been considerably increased during the past year. Where there was formerly but one night attendant on each side of the house there are now six. This change was found necessary on account of the increase in the number of suicidal and feeble and filthy cases, and also by the desire to put all epileptics under night care. In consequence of this improvement in the night service, chambers have been done away with to a very great extent. On the convalescent wards and on the wards where there is night service the room doors are left unlocked, thus giving the patients free access to the closets during the night. The advantage of discarding the objectionable and dangerous vessel is one which only a hospital physician can appreciate. . . . The proportion of night attendants to the average population is now one to sixty-six, whereas a year ago it was one to eighty-two. Fortunately, the time has passed when it was only thought necessary to keep the insane confined on the wards during the day and locked securely in their rooms at night. Among the many advances in asylum management during the past few years not the least has been the effort to make night care compare favorably with that of the day. . . . Upon the suggestion of Commissioner Brown, spray baths have been introduced in the infirmaries for both men and women. They have been found very satisfactory in every way, and far superior to the ordinary tub. By their use a great saving of water is effected, the bathing can be done in much less time, absolutely clean water for each patient is guaranteed, and, above all, the possibility of accident is entirely overcome. Many other improvements have taken place in regard to bathing,

<sup>\*</sup> Dr. Charles W. Pilgrim, now superintendent of the Hudson River State Hospital.

the most important being regular and systematic medical supervision. . . . The wards on the first floor on each side of the main building have been entirely renovated and refurnished, and they now compare favorably, in appearance and comfort, with the wards of any hospital in the State."

In the report of the Buffalo State Hospital for 1892 the managers state as follows: "The managers note with pleasure the efforts put forth to occupy and interest the patients. In every department employment is found for them—in the carpenter and paint shops, in the engine-house, in the bakery, in the kitchen, on the farm, at the barns, on the grounds, in the greenhouse, in the laundry, in the sewing room, and in the schoolroom. To this constant effort to find occupation for all who are able to do something we can but attribute much of the improvement and contentment of the inmates.

"It breaks up the monotony of institutional life, improves the health, occupies the mind to the exclusion of dwelling upon delusions, and distracts the attention of patients from their unhappy state. It also furnishes a vent for restlessness and much of the mischief idle hands find to do, not only among the inmates of asylums but in the outside world. One is impressed by this in contrasting the wards of a hospital to-day with those of a few years since, when listlessness and idleness were the prevalent conditions of life in an asylum. The two important factors to which must be attributed in a large degree the improvement of our hospitals are occupation and night attendance. They have changed these institutions from the former bedlams to the modern hospitals for the insane."

And again: "The hospital buildings proper have not been neglected, but have received a due share of attention. The wards of the A buildings have been tastefully painted and decorated and are now more cheerful and homelike. New furniture has been supplied where needed, additional pictures placed on the walls, and carpets and rugs of our own manufacture on the floors. Attention has been given to the plumbing; vent pipes and traps have been put upon the fixtures, and in all of the A wards two new enameled tubs have been put in the bathrooms.

"One of the corridors connecting the new ward building with the center has been furnished with desks, and is utilized for the patient's school during the morning hours and in the afternoon for the attendants' training school.

"This is now a marked feature of the administration of the hospital, and from its early inception has received the support of the board of managers. They are convinced, by the more intelligent care given to patients and by the success which has attended the nurses who have gone out from the school and entered upon private work, of the great value of this school to the hospital and community.

"We have thus hastily passed in review some of the more important changes and improvements which have been made in the hospital, on the grounds, and in the conduct of affairs during the year. We feel assured also that the moral and medical treatment of patients have received their full share of attention from the medical staff. They have been devoted to the duties respectively assigned to them

and have labored successfully to elevate the general standard of care,"

The medical superintendent of this hospital, in his report for the same year, states: "Under the new regulations regarding the commitment of the insane the number brought in restraint was still further diminished from preceding years. No restraint was used in the case of women patients, and only three men were brought in handcuffs and four in wristlets."

(To be concluded.)

# CERTAIN ERRONEOUS PRINCIPLES AND METHODS IN GYNÆCOLOGY.\*

By G. BETTON MASSEY, M. D.,

PHILADELPHIA,
PHYSICIAN TO THE GYN.ECOLOGICAL DEPARTMENT OF HOWARD HOSPITAL
AND TO THE SANATORIUM FOR THE TREATMENT OF
THE DISEASES OF WOMEN AND DISEASES OF THE NERVOUS SISTEM.

It is by no means my intention to canvass the whole field of gynæcology in this paper, pointing out all the views and practices that I regard as erroneous. Such a course would be at least open to the objection of wearying the listener, for the moot points in gynæcology as now practiced are many, and the day has long passed when questions of this character can be regarded as settled beyond dispute by the ipse dixit of an alleged authority, or even by the consensus of opinion and practice of many physicians. The history of medicine teaches many things, but nothing more clearly than that large bodies of the profession may grievously err in their views and practices.

My own views of present errors are merely given for what they are worth, as they are tested in the crucibles of practice and common sense.

Is gynæcological surgery synonymous with gynæcology? Probably the most fundamental error of the day in this matter is the tacit assumption of many that gynæcology is synonymous with gynæcological surgery. I have possibly dwelt upon this before, but it is none the less true, and I am impelled to repeat it, and drive it home into our inner consciousness by reason of that scientific quality of mind as well as matter-inertia, which permits us to change habits of thought but slowly when a certain impetus has been gained in the wrong direction. This assumption that the diseases of women are the exclusive domain of the surgeon had its bad results at its inception, but was at that time by no means so freighted with dangerous possibilities as at the present, when, under the stimulus of a reduced mortality due to the slowly perceived duties of surgical cleanliness, the most heroic operations are daily practiced by these alleged masters of the whole art of curing womanly ills. Gynæcology should be understood as embracing the whole field of the affections commonly found in women, particularly those likely to be confounded with purely local faults-such as disorders of the nervous, digestive, and eliminative systems.

I do not for a moment wish to decry the value and signal services of surgery in these affections; it is only the

<sup>\*</sup> Read before the Philadelphia Obstetrical Society, March 1, 1894.

assumption that this department of gynæcology is the whole of it that I desire to point out as an important error and one that is responsible for many radical mistakes in treatment.

Is removal the only proper course to pursue with diseased organs? A sufficient text upon which to arraign some of these erroneous views thus conceived and born may be found in a few words spoken by a visiting surgeon in a discussion in this society during the present winter. At the close of his remarks on a paper read by Dr. Goodell this speaker asserted his conviction that where seriously diseased structures were found in the pelvis he still regarded their removal as the only proper course. Without invidious distinction, this sentiment may be taken as the working creed of the whole body of surgical gynæcologists, who regard certain ultra-mechanical methods with which they are familiar as applicable to all diseases of women. But if the only proper course to pursue in pelvic diseases is to re move diseased organs, how happens it that this principle has not been applied to other portions of the body ? Typhoid fever, gastritis, cystitis, hepatitis and the whole list of organic inflammations are clearly due to local diseased organs, yet we do not hear of the removal of these structures being either proposed or practiced. It may be said, of course, that the preservation of life would be impossible should the organs be removed in these cases; but such questions of expediency do not have place when the parts affected are not more essential to life than the pelvic organs, yet we still fail to hear of any penes being removed for gleet or stricture, testes for mere orchitis, limbs for an arthritis, or eyes for a keratitis. It is even considered justifiable to remove the ovaries for an ecchymotic extravasation of blood into the broad ligament or surrounding cavities or tissues, when it is well known that a much larger hæmatoma of the orbit, a black eye, will get well in a few

But even if it were the practice to remove organs not hopelessly diseased in other departments of surgery, it would still be proper to protest against such a low estimate of medical responsibilities in this or any department, and to point out that even a cure of an affection gained by the loss of a portion of the human body is a confession of scientific incompleteness with which we should not be satisfied.

Prevailing Mechanical Methods Inconsistent with Recent Bacterial Discoveries.—A great majority of these hasty and useless amputations of pelvic organs that are still amenable to cure, as well as many ultra mechanical methods in minor gynæcology, arise in a misconception of the nature and course of certain affections essentially catarrhal in character. The advent of exact knowledge of the microbic nature of these affections, proving them to be primarily traceable to diseased mucous membranes, has laid to rest many theories of pelvic disease, notably those relating to displacements and obstruction, yet, sad to say, these same affections are still treated in accordance with the dead theories, and a large portion of the income of instrument-makers flows from their sale of pessaries and dilators.

Intrenched behind an old belief that the uterine con- uterus.

gestion and engorgement that accompanies backward and downward displacements of the uterus were secondary to the displacement, the method of treatment is the correction of the displacements, first, by mechanical means, in the hope that a proper position and easier circulation will cure the case. That relief will at times follow this procedure is unquestioned; but the far greater number in which it fails to either reduce the hyperplasia or the subjective symptoms proves that the reasoning is at fault. This mechanical theory of the causation of hyperplasia is in fact a unique survival amid the present facts of the true nature of endometritis and its sequelæ—the various atrophies and connective-tissue replacements of the uterine Modern pathology points clearly to microbic agencies as the initial cause of the more common alterations in the health of the endometrium and consecutive changes within the parenchyma, even if a trauma, such as a laceration, be the means of admitting the germs to a foothold within the tissues. Flexions are doubtless due to local, one-sided atrophies of the uterine muscular tissue, while downward and backward displacements are the conjoint effect of hyperplasia, tight lacing, and relaxation or injuries to the pelvic floor.

The most important conditions present therefore in endometritis, flexions, and displacements are histological alterations within the tissues of the uterus. Great relaxation of ligaments, and even considerable impairment of the pelvic floor, may exist without material alteration of the situation of the uterus, and without subjective symptoms of any kind, as can be readily proved by any one who examines any number of multiparous women who do not consider themselves ill. The majority of women, in fact, who have had three or more children present these symptoms of relaxation without descensus, and unless there is a descensus due to a still existent hyperplastic inflammation, or a proctocele or cystocele, they have no complaints to make.

In view, therefore, of the easily demonstrable histological changes always present in flexions and displacements that cause suffering to the patient, it is manifestly proper to combat the morbid processes within the uterus by curative agencies adapted to the conditions, rather than by distending and paralyzing the vagina in an effort to remove a remote consequence of the disease, or by excising a mere portion of the diseased organ. A restoration of tone and function to the parts should be the result of well-directed efforts.

The Cervical Laceration Myth.—The same objections lie against the idea that a healed tear of the cervix has any true pathological importance, unless the laceration, by virtue of its extent, interferes with pregnancy. The symptoms attributed to the tear are due to the consequences of microbic invasion of the uterus, and though the rest and hygienic accompaniments of the operation for repair at times favorably affect the patient for a while, there is rarely any improvement noted in cases suffering from symptoms traceable to the uterus. The cause of the suffering is not the hiatus in the lips of the uterus nor the much-maligned scar tissue at the apex, but lies in the chronically inflamed

To cure the patient we must cure the endometritis, metritis, or hyperplasia as well as any enfeeblement of the nervous system consequent upon them. After that is done it is time to consider the wisdom of repairing the tear, if it is a bad one. If hot water, glycerin tampons, and iodine to the vault have failed, the patient should be placed on mixed galvanic and faradaic treatment, applied within the cavity of the uterus by means of a pliant electrode covered with moist absorbent cotton. It is extremely rare that improvement does not show itself immediately, as the contractile effects of the two currents are efficiently assisted by the microbicidal and decongestive action of the positive pole of the galvanic current.

Oophorectomy as a Disease. - As to the buckets filled with ovaries and tubes that are nightly paraded in our societies, words fail me. The disease for which these organs are removed exists in the minds of the operators rather than in the bodies of the patients, and has stained the last quarter of the nineteenth century with an indelible blot on the fame of medical practice. I leave the discussion of this woful epidemic to posterity, and will merely remark that the catarrhal and inflammatory affections of the tubes and ovaries for which these organs are thus amputated are generally amenable to curative influences patiently prosecuted, chief of which is the direct application of the galvanic current to the uterus, or the indirect application of the same and the faradaic current to the ovary itself. Probably the most powerful means is the uterine method when it can be safely employed, for we can thus initiate a curative process at the point in the mucous tract where the initial inflammatory condition had its start, and where it still remains in most cases.

The Prevention of Ovarian Disease.—But a more easily applied remedy lies in the prevention of tubal and ovarian disease by a recognition that they are simply extensions upward of microbic infections of the uterus. In the early cure of virginal endometritis, subinvolution, and gonorrheal invasions by intra uterine galvanic applications, associated with proper hygienic measures, we may stamp out the disease as a conspicuous factor in modern life, even though hampered as we are with the catarrh-breeding environment of American climate and habits. It is while this affection is still in the uterine stage of its existence that these young women may be saved from the future invalidism of ovarian disease, with its unwelcome vista of a suggested sexless future; and I have had the pleasure of seeing a number of patients thus rescued, both from unsound health and from the irrevocable consequences of an unwisely suggested castration.

Endometritis the Initial Lesion in many Pelvic Diseases.

—In spite of the practical neglect of endometritis by most of our active gynæcologists, who are merely content to remove rather than cure its consequences, there can be no question of its great practical importance in the ætiology of pelvic inflammatory disease, and he who cures a chronic case accomplishes results of far-reaching consequence to his patient. I have already indicated my own methods in dealing with this affection in the paragraph on laceration.

Menorrhalgia and the Operative Production of Laceration.—Closely allied to this question is that of painful menstruction, for which I have suggested the term menorrhalgia as preferable to dysmenorrhea. To the minds of careful investigators the old theory that this symptom was due to a mimic labor with an obstructed outlet has been completely disproved. No accumulations have ever been shown to occur in these cases, and the fact that a large dilator can be inserted within the cavity of the uterus disproves the existence of any obstruction to the flow of the menstrual fluid. Spasmodic contractions of the circular muscular fibers of the internal os may be produced by the irritation of a sound, but it is by no means proved that these fibers are contracted at the time of flow. A case of my own, in which I inserted the sound during an attack of pain, tends to prove the contrary, for an internal os that admitted the sound with difficulty at other times was quite patulous during the pain. A rational review of this question is convincing that menstrual pain is due to either ovarian or nervous erethism, the actual attack being a neuro-muscular storm in a series of organs imperfectly prepared to functionate, the exciting cause being often a catarrhal endometritis, though by no means always. For a disease of such varied relationships and bearings it is manifestly improper to practice the routine method of dilatation, which is irrational, rarely of permanent benefit, harsh, and often productive of dangerous results. The causation and pathology teach the need of therapeutic measures to improve the general health and nerve tone, and to combat the local congestions and catarrhs if such exist; and the readiness with which these cases respond to such combined measures offers no excuse for resort to operations whose only rationale is a disproved theory. It surely does not need the many uncured cases that come under our observation to prove the impropriety of this operation, which produces the very lacerations so laboriously and expensively sewed up after

Dangerous Operations for Benign Tumors.—A different reason applies to any opposition I may express to operations for the removal of fibroid tumors of the uterus. These growths are distinct deformities of the uterus, and, when large, are deformities of the person. Surgical operations for their removal are therefore proper enough, and the question becomes one of expediency only.

It has been amply demonstrated that all small fibroids, and solid and interstitial varieties of large ones, are amenable to arrest and retrogression by the use of the Apostoli method of electrical treatment. In my own experience this has occurred in seventy-six out of eighty cases, in seven of which the tumor disappeared entirely. The claims of this method in preference to the knife are therefore of very great importance, particularly when the large mortality of the operation is contrasted with the slight mortality of the tumors left to themselves, and when it is also remembered that a successful hysterectomy renders the patient sexless, and leads so often to a troublesome hernia at the site of the abdominal incision. Degenerating or suppurating tumors do not permit us to select any other alternative than the knife.

Restoration of Function.—The highest aim of the gynæcologist should be the restoration of function, yet how seldom do we hear of this, in its broadest sense, being an ever-present consideration with the operator in gynæcology as it is practiced! The cure of sterility, it is true, is frequently aimed at, but a reader of our most recent works on the diseases of women will make wondrous excursions into the realms of antiseptic surgery and abdominal section, will read of gross diseases and endless amputations as remedies, but will probably see no mention whatever of the analogous conditions and weaknesses peculiar to their sex which surely women suffer from as well as men. The gynæcologist knows much of intestinal anastomosis and cholecystectomy, but nothing of matronal impotence. It is like the play of Hamlet without Hamlet. In these neglected fields lie some of the remote causes of pelvic disease and many of the more trifling complaints which mar the conjugal and social life of woman.

#### INGROWING TOE NAIL:

COTTING'S OPERATION,
WITH THIERSCH'S SKIN-GRAFTING ON THE SECOND DAY,
COMPLETE HEALING IN A WEEK.

REPORT OF FOUR CASES.

BY SINCLAIR TOUSEY, A.M., M.D.,

SURGEON-IN-CHIEF, ST. BARTHOLOMEW'S CLINIC'S ASSISTANT SURGEON, ROG-EVELT HOSPITAL, OUT-PATIENT DEPARTMENT;
CLINICAL ASSISTANT IN SURGERY,
NEW YORK FONT-GRADUATE MEDICAL SCHOOL.

The cases of ingrowing toe nail which are referred to the surgeon in private practice or which go to the dispensaries for treatment are the severe ones in which treatment by astringent applications (commonly tincture of iodine) and by suitably trimming the nail has failed to give relief. Every step is exceedingly painful, and, on examination, we find one side of the nail (commonly of the great toe) extending deeply into a mass of indurated tissue surmounted by a layer of exuberant granulations.

The treatment which I have always adopted has been Cotting's operation. Cocaine is injected hypodermically and no constriction is made about the toe. The scalpel is held vertically, with its edge forward and its point at the side of the nail close to the matrix, and is pushed vertically completely through the toe close to the side of the nail; then with a sawing motion the knife is carried forward, converting the part of the toe external to the nail into a flap. The edge of the knife is then turned backward and this flap is entirely severed by an oblique cut outward and backward. The nail is not cut at all and the matrix is not even exposed; but we have hollowed out the side of the toe so that the side of the nail projects at all points beyond the flesh. The area thus denuded is of about the size of a silver quarter of a dollar, and in Cotting's operation is left to heal by granulation. The after-treatment is extremely easy (with simple gauze for the first week and then gauze moistened with balsam of Peru, the dressings being changed every three days), but complete cicatrization takes at least three weeks and the surface requires a protective dressing for a week or two beyond that.

The length of time required for the after-treatment has led me to modify the operation by the employment of Thiersch's method of skin-grafting. It is impracticable to do this at a single sitting, as there are two or three spurting arteries and the capillary hæmorrhage is very free and persistent. My method has been to apply iodoform gauze and very firm pressure by cotton and bandages to control hæmorrhage without applying a single artery clamp, and two days later to do the grafting. The gauze is soaked with sterilized salt solution and is very gently removed from the raw surface. This can readily be accomplished without occasioning a drop of hæmorrhage. In each of the cases the graft has been taken without any anæsthetic and has been of such a size and shape that one graft has completely covered the surface. In three cases the graft was taken from the leg and in one from the arm. The arm, I think, is preferable, for should the patient ever happen to have an ulcer of the leg his or her mind would naturally revert to the time when nearly a square inch of skin was taken from the leg with a razor. (After a considerable amount of hospital and dispensary work, I have come to regard every woman as a candidate for an ulcer of the leg.) As to taking the graft without an anæsthetic: my patients were a boy and a girl, each about fifteen years old, a very nervous young lady about twenty, and a laboring man. None of them seemed to suffer and they all smiled when I asked them if it would have been worth while taking gas for. I have never employed cocaine in skin-grafting and do not know whether the grafts would be devitalized by it or not. [The thigh is an undesirable place to take the graft from, because of the relative difficulty of the dressings in an ambulant case.]

The dressing has consisted of rubber tissue and gauze moistened with sterilized sait solution (0.6 per cent.) and has been changed every other day for a week, at the end of which time the surface has been found healed, and a protective dressing of subnitrate of bismuth and gauze has been adopted for a week.

The cases in which the grafting would not be a successful addition to Cotting's operation are those in which there is paronychia with cellulitis of the entire toe. For ordinary cases it presents no difficulty whatever.

The reason for selecting this operation in preference to Angier's operation (in which a section of the side of the nail and the corresponding portion of the matrix are excised and the wound is closed by sutures) is that in the only cases which have come under my observation in which the latter operation had been performed (five in number) the patients have come to me for treatment for a recurrence of the trouble and have been permanently cured by the, other operation.

My cases of Cotting's operation have numbered thirty (including those of grafting) and the only case of failure has been one in which Angier's operation had previously been performed and in which Cotting's operation had to be supplemented by evulsion of the nail.

# NEW YORK MEDICAL JOURNAL, A Weekly Review of Medicine.

Published by D. Appleton & Co. Edited by FRANK P. FOSTER, M. D

NEW YORK, SATURDAY, MAY 19, 1894.

THE PROPOSED REDUCTION OF THE MEDICAL CORPS OF THE ARMY.

WE lately expressed our disapproval of the bill reported to the House of Representatives by its committee on military affairs, proposing to reduce the number of medical officers of the army. In our article on this subject we treated it with an eye to the efficiency of the medical department, which we said would be seriously impaired if the proposed action was carried into effect. We have since then been made acquainted with the views of many gentlemen connected with the army, including both line and staff officers, concerning this point, and they are all agreed that to curtail the number of officers of the medical corps would be to run a great risk of embarrassing the operations of the army; furthermore, they all concur in the opinion that recourse to the services of medical men hired from civil life to attend upon the sick and wounded soldiers and their families would, on the whole, result not in any saving of money, but on the contrary in a very considerable additional expenditure. By no means the most inconsiderable of the ways in which such a procedure would prove prejudicial is that of its substituting in the examination of recruits the services of persons not specially trained to such examinations for those of the regular commissioned officers of the medical corps, most of whom have had years of experience and special training in this sort of work. In the matter of making reports also and in many diverse duties which a medical officer of the army is called upon to perform, quite apart from mere attendance upon the sick, the hired civilian practitioner, whatever his purely professional attainments and wisdom might be, would be almost sure to fall short of the requirements of the service.

Although efficiency is the first thing to be considered, there is another aspect of the matter that concerns the medical profession very intimately. The medical corps of the army is a body of men of which the American medical profession is justly proud; its members have proved themselves possessed of executive ability to an unusual degree, as was shown by their management of the military hospitals during the late civil war; they have contributed, as never did the medical corps of any army contribute before, to the advancement of military medicine, as may be learned from the Medical and Surgical History of the War of the Rebellion and from the numerous references to that great work which are to be found in subsequent medical literature all over the country; they have shown their appreciation of medical literature in general by the preparation of a work of no lesser importance, the Index-catalogue of the

Library of the Surgeon General's Office. Is it fair to the medical profession of the country that a corps of which, as its representative, it entertains such an exalted opinion should be so reduced in numbers that the utmost amount of exertion, physical and mental, of which its members are capable should be called for for the performance of their routine duties, leaving them absolutely no time in which to prosecute further work of such a character as that which has won for them, and, through them, for the American medical profession, the respect and admiration of the civilized world? The medical profession of the country can, we believe, give but one answer to this question, and we call upon them to express their feeling on the subject in such a way that Congress will feel compelled to pay attention to it. Let individual members of the profession communicate with individual congressmen, and let medical organizations throughout the country express themselves in their corporate capacity; let Congress be made to understand, in short, that the action proposed is not only, in the opinion of the medical profession, a petty piece of false economy-saving at the spigot and wasting at the bunghole-but also an affront to the profession of medicine. Such action, in our opinion, ought to be taken, and to be effective it should be taken without delay.

#### ARTIFICIAL RESPIRATION IN CHLOROFORM POISONING.

In the Hospital for April 28th there is a paper on this subject by Sir Benjamin Ward Richardson, M. D., F. R. S., in continuation of a previous paper in which the author had pointed out the risks that might arise from the use of electrical excitation in cases of collapse due to chloroform. In this article he places artificial respiration as the first and foremost among the only rational methods that he thinks practicable to bring about recovery. He does not assume, however, that death from chloroform is due purely to failure of respiration, because there is always some primary failure of the heart; but this, he says, does not mean actual arrest of the heart's motion. The fact that after death by chloroform the heart is usually found still moving in the lower animals has led, he continues, to the natural idea that the organ is still performing vital functions, and therefore that death must occur from failure of the respiration. But he points out that there is a deception on this point. Mere rhythmical motions of the auricles and ventricles of the heart, he goes on to say, do not necessarily mean vital motion. He has noticed that the heart has three grades of motion: (a) full vital motion of propulsion, such as goes on during perfect consciousness; (b) partial vital motion of propulsion, such as goes on while there is life with breathing, but without consciousness, as in syncope, catalepsy, and anæsthesia; (c) passive motion of the auricles and ventricles without propulsion and with arrested respiration, or what may be called respiratory death-in other words, the motion of collapse, most commonly presented in collapse from chloroform. In this state the heart is reduced in volume-that is, it is contracted and contains very little blood. It is as if it were passing into rigor mortis, and, in fact, when

it does not come back to its natural action, it does pass into this condition, which means its more complete arrest and, as a natural consequence, its death and that of the body as a whole. That the respiratory muscles have failed in their function during this state is due indeed to the circumstance that they are not receiving from the heart the amount of blood which they require, and therefore have failed in their working power. Meanwhile the lungs, owing to the passive contraction of their elastic structure, which continues independently of the blood supply, become resistant and to an extent collapsed. Moreover, the elastic resistance of the pulmonary artery progresses, giving rise to opposition to the entrance of the blood into the lungs, an opposition which the enfeebled heart has little power to overcome. That this opposition is exceedingly great may be shown by endeavoring with a syringe fixed in the pulmonary artery to force a current over the lesser circulation.

These facts, says the author, lie at the root of all endeavors to start the lesser circulation in chloroform collapse. If we do not understand them we are easily led to suppose that the whole difficulty lies in the failure of the respiratory current, whereas, partly at any rate, the failure is in the heart itself and may be there primarily, although immediately after death that organ may appear to be alive. This being the case, it might be supposed that artificial respiration would never of itself suffice to restore the individual, but the author has seen it do so in the most evident manner. While watching the motions of the heart in the third degree described, artificial respiration being carried on, he has seen the heart pass into the second degree and then into the first, with almost immediate recovery of the vital muscular movements throughout the body and with a renewal of attempts at spontaneous respiratory movements. These phenomena, he says, are most remarkable and not to be understood properly without being actually seen. There is first, as it were, a leap of cardiac motion from the third or feeblest stage into the second, or, as he would call it, the syncopal or cataleptic. In this second stage the heart increases in volume and there is feeble pulsation in the pulmonary artery. Then there is a second leap in which the cavities of the heart suddenly become tense with blood; the organ enlarges to twice the size that it had in the third degree. The pulmonary artery is distended and pulsates forcibly; the lungs become charged with blood; the left half of the heart fills; the aorta begins to pulsate strongly and accurately; all the muscles receive their new supply of blood; respiratory movements are made accurately-in a word, vitality is restored. The author affirms that artificial respiration is the only means now at our command to bring about resuscitation. In the lower animals he has seen it succeed as late as seven minutes after all external evidences of life had ceased, but its success or failure depends upon varying circumstances. It is a very great obstacle to its success for the temperature of the day to be very high, for in that case the blood coagulates quickly and plugging of the pulmonary circuit takes place. Extreme cold also is an obstacle. The most favorable temperature is that of about 60° F. Again, any rough motion of the body is an obstacle, for that tends to air of severity and said she did not like to sign such things un-

arrest what little remaining motion there may be in the heart. Finally, too violent artificial respiration is itself an obstacle, for when the lungs are inflated vigorously and rapidly the very pressure which they make on the heart in the closed thorax is sufficient to stop the feeble cardiac pulsation.

It follows from these observations, says the author, that the ordinary methods of artificial respiration, such as Sylvester's and Marshall Hall's, must be injurious, as they tend to reduce the power of the feebly moving heart. What is really wanted is quick, gentle emptying of the lungs of the air charged with chloroform which they hold, with gentle refilling of the chest with fresh air introduced without undue pressure, so that it may reach the feeble current of blood which may possibly be making its way over the pulmonary circuit. In the absence of apparatus, mouth-to-mouth insufflation is the best method. By fixing a rubber tube to the nostril of one of the lower animals, and emptying and filling the animal's chest through it, very gently, recovery from the deepest collapse can almost always be effected if the temperature of the air is moderate. It does not appear that the presence of carbon compounds in the operator's breath does any material amount of injury, and in the exhaled breath there is always oxygen enough to start respiration anew. The objection lies in the personal act of setting up breath-to-breath respiratory actions, and the author has endeavored to meet this objection by means of double-acting hand-bellows, made of rubber, which are exhausted by one bulb and filled by another, so that by the same motion of the hand the patient's chest is emptied and refilled. Any ordinary bellows will answer if these are not at hand. The nozzle is placed in one nostril, and the other nostril and the mouth are closed with the hand; then by expanding the bellows the air may be drawn out of the chest, and by gently compressing them the chest may be filled. It is not at all necessary to imitate the natural rate of the movements of respiration; the gentler the movements of suction and insufflation the better, eight to ten of each in a minute being quite sufficient.

#### MINOR PARAGRAPHS.

#### A LADY NOTARY AND A LUNACY CERTIFICATE.

THERE are several lady notaries in New York. From our limited experience with them we believe that, as a rule, they conduct the business of their office in a manner that leaves nothing to be desired. One of our professional brethren, however, has lately had to deal with a female notary who seems not only to have a gross misconception of her duties, but also to consider herself privileged to asperse the motives of persons concerning whose doings she knows nothing. Our colleague gives the story of his encounter in Thursday's Sun. He and another physician, having examined a lunatic, made out the certificate prescribed by law in such cases, and went in quest of the nearest notary, who happened to be a woman, that they might swear to it in due form. The notary began to read the long document; she read it through again and again, in spite of her visitors' hints that they were in haste and wished her to perform her function without delay. Finally she assumed an

less she knew all about them—she had got into so much trouble about them. After she had made repeated remarks to this effect she was told by one of the gentlemen, whose patience was by this time exhausted, that if she felt at all suspicious about the paper they would not ask her to sign it; they would take it and go elsewhere. At this she ungraciously cast the document at the gentlemen and said angrily: "Here, take it, and go elsewhere; if I was not suspicious at first, your great haste would certainly make me so." Surely, none of our readers needs to be told that a notary has nothing to do with the contents of a document to which his or her signature and official seal as a notary are to be affixed.

#### THE CITY LUNATIC ASYLUMS.

The state of affairs at the lunatic asylums on Ward's Island, as portrayed in the New York Herald during the week, seems to call for immediate investigation, and the Mayor is to be commended for having so promptly called upon the State Commission in Lunacy to institute one. The Herald's charges bear upon almost everything connected with the shelter, feeding, and medical care of the pauper insane, and it can not be said that they are inspired by malicious or ill-informed persons. There is too much reason to believe that they are not in the least overdrawn. The people of New York are willing and anxious to do everything possible to alleviate the sad lot of their insane, and it is monstrous that they should be foiled in their efforts in that direction. It is to be hoped that the proper authorities will lose no time in setting a searching inquiry in motion.

# THE MARINE-HOSPITAL BUREAU'S ABSTRACT OF SANITARY REPORTS,

We have received the eighth volume of this weekly publication, for the year 1893. It contains 1,300 pages of text, together with a very satisfactory index. These abstracts are of more than temporary value, and the bound volumes will undoubtedly be found useful in a high degree by sanitarians for many years to come.

#### A BOVINE TUBERCULOSIS COMMISSION.

A Law recently enacted by the State of New York provides for the appointment of a commission, consisting of a physician, a veterinarian, and three members of the State Dairymen's Association, to report in regard to needed legislation on tuberculosis in cattle. The sum of \$9,000 is appropriated to meet the commission's expenses.

#### ITEMS, ETC.

The Third Congress of American Physicians and Surgeons will be held in Washington on Tuesday, Wednesday, Thursday, and Friday, May 29th, 30th, 31st, and June 1st, under the presidency of Dr. Alfred L. Loomis, of New York. The general sessions will be held in the afternoon in Metzerott's Music Hall, corner of Twelfth and F Streets. On Thursday evening the president's address will be delivered, on The Influence of Animal Experimentation on Medical Science, and after that there will be a reception.

At the session of Tuesday afternoon, May 29th, at 3.30 P. M., under the direction of the Association of American Anatomists, the subject of Morphology as a Factor in the Study of Disease will be opened with a paper by Dr. Harrison Allen, of Philadelphia, and discussed by Dr. Thomas Dwight, of Boston, Dr. Frederic H. Gerrish, of Brunswick, Me., Dr. Frank Baker, of Washington, and Dr. Burt G. Wilder, of Ithaca, N. Y.

On Wednesday afternoon, May 30th, there will be two sessions, one at two P. M., under the direction of the American Climatological Association, at which papers on Sewer Gas will be read (Chemical, Physical, and Bacteriological Studies upon Air over Decomposing Substances, with Special Reference to their Application to the Air of Sewers, by Dr. Alexander C. Abbott, of Philadelphia; The Effect of Sewer Gas in the Production of Disease, by Dr. Abraham Jacobi, of New York; and Sewer Gas as a Cause of Throat Disease, by Dr. Beverley Robinson, of New York [discussion by Dr. Victor C. Vaughan, Dr. William H. Welch, Dr. J. Solis-Cohen, Dr. Carl Seiler, and others]). The other session, at 3.30 P. M., will be under the direction of the American Dermatological Association. The programme includes the following: The Distribution and Control of Leprosy in North America (the distribution, by Dr. J. Nevins Hyde, of Chicago [discussion by Dr. James E. Graham, of Toronto]; the Diagnostic Features and Treatment, by Dr. P. A. Morrow, of New York [discussion by Dr. A. Van Harlingen, of Philadelphia]; the Contagiousness, Prophylaxis, and Control, by Dr. James C. White, of Boston [discussion by Dr. George H. Fox, of New York, Dr. Joseph D. Bryant, of New York, and Dr. Walter C. Wyman, of the Marine-Hospital Service]). At 7 P. M. there will be a dinner to the guests of the congress at the Arlington Hotel,

On Thursday afternoon, May 31st, there will be two sessions, one, at 2 p. m., under the direction of the American Association of Genito-urinary Surgeons, at which the subject of Nephritis in its Surgical Aspects will be opened with a paper by Dr. Edward L. Keyes, of New York, to be followed by one on The Bacteriology of Nephritis, by Dr. George M. Sternberg, of the army (discussion by Dr. George Chismore, of San Francisco, Dr. L. Bolton Bangs, of New York, and Dr. Francis S. Watson, of Boston). At the other session, at 3.30 p. m., under the direction of the American Gynæcological Society, the subject of The Conservative Surgery of the Female Pelvic Organs will be treated of in papers read by Dr. William M. Polk, of New York, and Dr. William Goodell, of Philadelphia.

On Friday afternoon, June 1st, there will be a business meeting at 1.30 P. M., after which two scientific sessions will be held. At the first, at 2 P.M., under the direction of the American Laryngological Association, the subject of The Surgery of the Accessory Sinuses of the Nose will be discussed by Dr. F. H. Bosworth, of New York, Dr. J. N. Mackenzie, of Baltimore, Dr. J. H. Bryan, of Washington, and Dr. John O. Roe, of Rochester, N. Y. The second session, at 3.30 P. M., will be under the direction of the American Neurological Association. Papers are to be read as follows on the subject of The Influence of Infectious Processes on the Nervous System: The Pathology and Ætiology, by Dr. James J. Putnam, of Boston; the Relation to General Nervous Diseases, by Dr. E. C. Seguin, of New York; the Relation to Mental Disease, by Dr. Charles K. Mills, of Philadelphia; and the Therapeutics, by Dr. F. X. Dercum, of Philadelphia.

Of the constituent bodies, the American Ophthalmological Society will meet at the Arlington Hotel, Ladies' Parlor No. 2, beginning on Wednesday, under the presidency of Dr. George C. Harlan, of Philadelphia. The programme is as follows: Two Recent Magnet Operations—one an Ideal Success, the other a Total Failure, by Dr. H. Knapp; A Demonstration of some Photo-micrographs of the Human Retina, by Dr. William F. Norris; The Practical Value of the Ophthalmometer, by Dr. Edward Jackson; Family History of Irideremia and Coloboma Iridis; Cataract Operation on Two Members, by Dr. D. De Beck; A Clinical and Microscopical Study of Two Cases of Glaucoma associated with Intra-ocular Hæmorrhages, and Some Additional Studies upon the Clinical Value of Repeated Careful

Correction of Manifest Refractive Error in Plastic Iritis, by Dr. C. A. Oliver; Tumor of the Optic Nerve, by Dr. Swan M. Burnett; Degeneration in the Retinal Vessels with Hæmorrhages in the Retina and Vitreous in Gouty Patients, and Recent Experiences in the Treatment of Detachment of the Retina, by Dr. C. S. Bull; Pseudo-erysipelas Periocularis Medicamentosa, by Dr. Edward Friedenberg; Some Typical Examples of Subnormal Accommodative Power, The Ophthalmoscope does not always reveal Latent Hypermetropia, with Notes of a Case, and A Case of Ophthalmitis Suppurativa following Discission of Capsular Opacity, by Dr. S. Theobald; Removal of Steel from the Vitreous, by Dr. E. E. Holt; Colloid Disease in the Macular Region Analogous in Appearance to the so-called Drüsen in the Nerve Head, Epithelioma of the Lid, Excision and Transplantation of Skin without a Pedicle, and Concerning Monocular Diplopia, with Cases, by Dr. G. E. De Schweinitz; Two Cases of Sympathetic Inflammation, and A Portable Perimeter, with its Apology for Existence, by Dr. F. M. Wilson; So-called Muscular Asthenopia, by Dr. G. W. Hale; The Practical Value of Low-grade Cylinders, by Dr. J. A. White; Results of Repeated Examinations of the Eyes of the Boys in the Penn Charter School, of Philadelphia, by Dr. B. A. Randall; Foreign Bodies in the Orbital Cavity, by Dr. W. B. Johnson; Rupture of the Lymph Sheath of a Retinal Vein, by Dr. A. G. Heyt; The Halo Symptom in Glaucoma, by Dr. S. O. Richey; A Case of Melanotic Round-celled, Giant-celled Sarcoma of the Lid with Myxomatous Degeneration, by Dr. W. H. Wilmer; Three Cases of Ectropion Uveze, by Dr. L. Howe; A Double Case of Neuro-paralytic Keratitis lasting Ten Years, by Dr. P. A. Callan; and A Modification of the Operation for Canthoplasty, A Case of Binocular Coloboma of the Lens without Coloboma of Iris or Chorioid and with Accommodation Retained, and A Case of Binocular Luxation of the Lens, by Dr. C. F. Clark.

The American Otological Society will meet at the Arlington Hotel, in Ladies Parlor No. 1, beginning on Tuesday, under the presidency of Dr. Gorham Bacon, of New York. The programme is as follows: Otitic Brain Abscess-Opening of the Mastoid, Tympanum, and Skull-Evacuation of the Abscess-Hernia Cerebri-Evacuation of Another Abscess-Recovery, by Dr. H. Knapp; Five Deaths following Suppurative Otitis, and Two Autopsies, by Dr. F. M. Wilson; The Conservative Treatment of Mastoid Inflammation, by Dr. Ralph W. Seiss; Remarks on the Treatment of Chronic Purulency of the Ear, by Dr. Samuel Sexton : Chronic Tympanic Vertigo (so-called Ménière's disease) ; its Relief by Surgical Liberation of the Stapes, by Dr. Charles H. Burnett; The Value of Middle-Ear Operations as a Means of Improving the Utility of the Organ of Hearing, by Dr. Edward B. Dench; Statistical Studies of the Foramen of Rivinus and of the Axis of the External Meatus in their Relations to Intratympanic Surgery, by Dr. B. Alexander Randall; An Insufflator for applying Powder to the External Auditory Canal, by Dr. Walter B. Johnson; and Exhibition of Photographs of the Temporal Bone and Membrana Tympani, by Dr. Gorham Bacon.

The American Neurological Association will meet at the Cosmos Club, corner of H Street and Vermont Avenue, beginning on Tuesday, under the presidency of Dr. B. Sachs, of New York. The programme is as follows: Report of a Case of Spinal Syphilis and one of Intracranial Syphilis, with Microscopical Specimens, by Dr. Landon Carter Gray, of New York; Merycism, by Dr. William A. Hammond, of Washington; Inebriety as a Disease Analytically Studied, by Dr. R. M. Phelps, of Rochester, Minn.; A Case of Myxmedema treated with Sheep's Thyreoid, and Craniectomy in a Child Two Years Old, by Dr. Samuel Ayres, of Pittsburgh; The Genesis of Hallucinations, Illusions, and Delusions, by Dr. H. A. Tomlinson, of St. Peter: A Case of Pontine Embolism, with Paralysis of Ocular

and of Orbiculo-palpebral Movements of One Side and of the Limbs on the Other, with Remarks on Focal Lesions in the Pons, by Dr. C. K. Mills and Dr. John Zimmer, of Philadelphia; Thyreoidectomy in a Case of Graves's Disease, by Dr. J. Arthur Booth, of New York; Crossed Knee-jerks, by Dr. Guy Hinsdale and Dr. J. Madison Taylor, of Philadelphia; The Insanity of Puberty and Adolescence, by Dr. Henry R. Stedman, of Boston: Lumbar Puncture (Quincke) for the Withdrawal of Cerebro-spinal Fluid, by Dr. William Browning, of Brooklyn; Gastro-intestinal Neurasthenia-i. e., Nervous Dyspepsia, by Dr. Leonard Weber, of New York; Some Problems relating to the Cerebral Fissures, and Exhibition of a Suicide's Brain, with Two Pistol-ball Wounds, by Dr. Burt G. Wilder, of Ithaca, N. Y.; Exhibition of a Neurological Percussion Hammer, by Dr. William C. Krauss, of Buffalo; Cerebral Œdema, by Dr. George J. Preston, of Baltimore; The Non-operative Treatment of Metatarsalgia, by Dr. V. P. Gibney, of New York; A Case of Exophthalmic Goître Cured by Thyreoidectomy, by Dr. Frederick Peterson, of New York; Cerebral Hæmorrhage: Notes on its Cause and Premonitory Symptoms, and The Cortical Localization of the Cutaneous Sensations, by Dr. Charles L. Dana, of New York; Exhibition of Sections from the Midbrain, Pons, Medulla Oblongata, and Spinal Cord from a Case of Chorea, by Dr. James Hendrie Lloyd, of Philadelphia; Report of a Case of Amyotrophic Lateral Sclerosis in a Child, by Dr. Charles Henry Brown, of New York; The Significance of the Exaggerated Knee-jerk and Ankle-clonus, and their Relation to Diagnosis, by Dr. Græme M. Hammond, of New York; A Case of Congenital Hydrencephalocele, and A Case of Infantile Hemiplegia, Imbecility, and Epilepsy-Craniotomy-Marked Improvement, by Dr. Edward B. Angell, of Rochester, N. Y.; Experimental Investigations of the Physical and Chemical Action of the Galvanic Current upon the Living Organism, by Dr. George W. Jacoby and Dr. F. Schwyzer, of New York; Report of a Case of Diffuse Myelitis following Spastic and Choreic Symptoms of Three Years' Duration, with Specimens, by Dr. F. X. Dercum, of Philadelphia; and Traumatism as a Cause of Locomotor Ataxia; a Critical Examination of the Evidence, including a Report of Three Cases, by Dr. Morton Prince, of Boston.

The American Gynacological Society will meet in the Lecture Room of the Columbian University, corner of 15th and H Streets, under the presidency of Dr. William T. Lusk, of New York: The programme was published in the Journal for April 28th.

The American Dermatological Association will meet in the new Reception Room of the Arlington Hotel, under the presidency of Dr. Robert B. Morison, of Baltimore. The programme was published in the Journal for April 28th.

The American Laryngological Association will meet in the Arlington Hotel, Parlors D and E, under the presidency of Dr. D. Bryson Delavan, of New York. The programme was published in the Journal for May 5th.

The American Climatological Association will meet in the Parlor at Wormley's Hotel, corner of Fifteenth and H Streets, beginning on Tuesday, under the presidency of Dr. Andrew H. Smith, of New York. The programme is as follows: Alimentation in Pulmonary Disease (president's address), by Dr. Andrew H. Smith, of New York; The Relation which Alimentation should bear to Oxygenation in Lung Diseases, by Dr. Boardman Reed, of Atlantic City; The Methods and Value of Supervised Exercises and Diet in the Prophylaxis of Pulmonary Phthisis, by Dr. Glentworth R. Butler, of Brooklyn; The Importance of Mouth Cleanliness in the Prevention of Disease, by Dr. Clarence C. Rice, of New York; A Plea for the Earlier Recognition of Pulmonary Tuberculosis and the Adoption of

Proper Climatic Treatment, by Dr. H. B. Moore, of Colorado Springs; Three Years' Experience in the Sanitarium Treatment of Pulmonary Disease near Boston, by Dr. Vincent Y. Bowditch, of Boston; Creosote, Guaiacol, and Benzoyl of Guaiacol in Phthisis, by Dr. Roland G. Curtin, of Philadelphia; Shall Anything be Done by Legal Authority to Prevent the Spread of Tuberculosis? by Dr. Frederick I. Knight, of Boston; Further Report of Cases of Phthisis Treated at Colorado Springs, by Dr. S. E. Solly, of Colorado Springs; The Condition of the Heart in Diabetes and its Relation to Diabetic Coma, by Dr. Leonard Weber, of New York; Report of Cases of Chronic Heart Disease Treated by the Schott Method of Baths and Gymnastics, by Dr. Robert H. Babcock, of Chicago; A New and Distinguishing Sign of Latent Aneurysm of the Aorta, by Dr. W. C. Giasgow, of St. Louis; Musical Nomenclature in Physical Diagnosis, by Dr. J. Hilyard Tyndale, of New York; Ozone in Phthisis, with Special Reference to the Pneumatic Cabinet, by Dr. Charles E. Quimby, of New York; The Comparative Rarity of Phthisis in the Highlands of Pennsylvania and the Adjacent Counties of New York, by Dr. Guy Hinsdale, of Philadelphia; Meteorological Data of Colorado, by Dr. Samuel A. Fisk, of Denver; Sensible Temperatures, by the Hon. Mark W. Harrington, Chief of the Weather Bureau, Washington; Beri-Beri, by Dr. Judson Daland, of Philadelphia; Some Practical Observations on So-called Malaria, by Dr. W. H. Daly, of Pittsburgh; Shock in Acute Disease, by Dr. John H. Musser, of Philadelphia; and The Physical Signs of Cellular Œdema of the Lung Considered in their Relation to the Pathological Changes, by Dr. W. C. Glasgow, of St. Louis.

The Association of American Physicians will meet in Hall No. 2 of the Columbian University, corner of Fifteenth and H Streets, beginning on Tuesday, under the presidency of Dr. Reginald H. Fitz, of Boston. The programme was published in the Journal for May 12th.

The American Association of Genito-urinary Surgeons will meet at the Shoreham Hotel, beginning on Tuesday, under the presidency of Dr. George Chismore, of San Francisco. The programme was published in the Journal for May 12th.

The American Orthopædic Association will meet in the Preparatory Department of the Columbian University, H Street, between Thirteenth and Fourteenth Streets, beginning on Tuesday, under the presidency of Dr. A. M. Phelps, of New York. The programme was published in the Journal for May 12th.

The American Physiological Society will meet in the Physical Laboratory of Columbian University, Fifteenth and H Streets, beginning on Tuesday, under the presidency of Dr. Henry P. Bowditch, of Boston. The programme is as follows: The Effect of Fatigue on the Rate of Transmission of Nerve Force, by Dr. H. P. Bowditch; The Physiological and Therapeutical Action of Nuclein, by Dr. V. C. Vaughan; Remarks on the Qualitative Determination of Ptyalinogen and Pexinogen, by Dr. J. W. Warren; Some Points on the Chemistry of Muscle, by Dr. G. N. Stewart; Demonstration of the Effect of Calcium Salts on the Contractility of the Heart, by Dr. W. H. Howell; Circulation Time in Organs, by Dr. G. N. Stewart; A Study of the Volume Changes in Muscle during Activity and Rest, by Dr. G. W. Fitz; Exhibition of Plethysmographic Curves during Sleep, by Dr. W. H. Howell; On the Employment of Cerebral Pressure as a Means of Anæsthesia, by Dr. G. T. Kemp; Exhibition of a New Cannula Coupler (modification of the old French form), by Dr. G. T. Kemp; On the Pleurocardiogram and the Nature of Cardio-pneumatic Movements, by Dr. S. J. Meltzer; Preliminary Note on Cerebral Centers of the Bladder, by Dr. Isaac Ott; Some Facts bearing on the Action of Strychnine on the Spinal Cord, by Dr. A. R. Cuhsny; On Respiratory Paths in the Spinal Cord, by Dr. W. T. Porter;

Experiments upon Reflex Vaso-constriction and Vaso-dilatation, by Dr. W. H. Howell; and Preliminary Report of Experiments on the Reflex Time of Winking, A Short-circuiting Commutator affording Making or Breaking Induction Shocks, A Hand Rest to be used with the Ergograph, and A Non-oxidizable Mercury Key, by Dr. W. P. Lombard.

The American Padiatric Society will meet at the Arlington Hotel, in Parlors A and B, beginning on Tuesday, under the vice-presidency of Dr. F. Forchheimer, of Cincinnati. The programme was published in the Journal for April 28th.

The Association of American Anatomists will meet in the Preparatory Department of the Columbian University, H Street, between Thirteenth and Fourteenth Streets, beginning on Tuesday, under the presidency of Dr. Harrison Allen, of Philadelphia. The programme is as follows: The Study of the Human Cranium, and On the Shortening of the Face-axis in the Evolution of the Mammalia, by Dr. Harrison Allen, of Philadelphia; Identity of Structure of Protoplasm with that of Striped Muscle, by Dr. Carl Heitzmann, of New York; The Relation of the Olfactory to the Cerebral Portion of the Brain, and Notes on the Anatomy of the Orang, by Dr. B. G. Wilder, of Ithaca, N. Y.; The Perinæum and the Perineal Body, by Dr. D. K. Shute, of Washington; The Theoretical Anatomy of the Sympathetic System, by Dr. W. P. Carr, of Washington; Methods of Estimating the Height from Parts of the Skeleton, by Dr. Thomas Dwight, of Boston; In our Two Years' Study of Anatomy, What Part of the Subject should be covered in the First Year's Work? What Part in the Second? by Dr. A. D. Brown, of Chicago; A Plea for a Methodically Written Text-book on Anatomy, by Dr. Edmund Souchon, of New Orleans; The Terminology of the Nerve Cell, by Dr. Pierre A. Fish, of Ithaca, N. Y.; A Study of the Muscular Tunic of the Large and Small Intestine of Man in the Region of the Cæcum, and A Note in the Occurrence of the Scapulo-clavicular Muscle, by Robert Orton Moody, Yale University, New Haven; and The Female External Genital Organs, a Criticism on Current Anatomical Description, by Dr. D. S. Lamb, of Washington.

The American Surgical Association will meet in the Main Hall, Preparatory Department, Columbian University, 1825 H Street, beginning on Tuesday, under the presidency of Dr. J. Ewing Mears, of Philadelphia. The programme was published in the Journal for March 24th.

On Thursday evening there will be a reception by the President of the United States at the Executive Mansion.

The Gouverneur Hospital.—The sum of \$200,000 has been appropriated for the construction of additional buildings.

The Medical Society of the State of Pennsylvania.—At the annual meeting, held this week, Dr. John B. Roberts, of Philadelphia, was elected president for the ensuing year.

Niagara University.—The annual commencement of the Medical Department was held on the 9th inst. The degree of M. D. was conferred on fourteen candidates. The valedictory address was delivered by Harlow C. Curtiss, M. A., professor of medical jurisprudence.

Changes of Address.—Dr. Hermann Goldenberg, to No. 22 East Sixty-third Street; Dr. Frederick Peterson, to No. 60 West Fiftieth Street; Dr. J. E. Sheppard, to No. 147 Remsen Street, Brooklyn.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending May 12, 1894:

MARMION, R. A., Surgeon, is directed to hold himself ready to relieve Bright, G. A., Medical Inspector, on the U. S. Steamer Newark.

- Harmon, G. E. N., Surgeon. Ordered to the U. S. Steamer Monongahela. June 1, 1894.
- Barnum, W. M., Assistant Surgeon. Ordered to the U. S. Steamer Monongahela. June 1, 1894.
- STEELE, J. M., Surgeon. Detached from the U. S. Steamer St. Louis and ordered to League Island Navy Yard.
- Beyer, H. G., Surgeon. Detached from the Naval Academy and ordered to the U. S. Steamer Bancroft.
- BIDDLE, CLEMENT, Passed Assistant Surgeon. Detached from the League Island Navy Yard and ordered to the Marine Rendezvous, Philadelphia, Pa.
- Leys, J. L., Assistant Surgeon, is granted one month's leave of absence, with permission to go abroad.
- Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 29 to May 12, 1894:
- CLEARY, PETER J. A., Major and Surgeon. So much of Par. 13, S. O. 79, A. G. O., April 3, 1894, as assigns him to duty at Fort Wingate, New Mexico, is revoked.
- DE Witt, Calvin, Major and Surgeon, is granted leave of absence for two months, to take effect on or about May 1, 1894, with permission to go beyond the sea.
- EVERTS, EDWARD, Captain and Assistant Surgeon, is granted leave of absence for two months, on surgeon's certificate of disability, to take effect when his services can be spared, with permission to leave the Department of the Colorado.
- Kulp, John S., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Sheridan, Illinois, and ordered to Fort Spokane, Washington, for duty.
- MACAULEY, C. N. BERKELEY, Captain and Assistant Surgeon, is relieved from duty at the United States Military Academy, West Point, N. Y., and ordered to duty at Fort Wingate, New Mexico, relieving Matthews, Washington, Major and Surgeon, who, on being thus relieved, will repair to Washington, D. C., and report in person to the Surgeon General for temporary duty in his office.
- McVay, Harlan E, First Lieutenant and Assistant Surgeon. Par. 2, S. O. No. 86, A. G. O., April 12, 1894, assigning him to the station at Angel Island, California, is revoked. He will be relieved from duty at Fort Huachuca, Arizona, and will report for duty at the Presidio, California, relieving Willow, Charles, First Lieutenant and Assistant Surgeon, who, after thus being relieved, will report for duty at Angel Island, California.
- Wells, George M., First Lieutenant and Assistant Surgeon, will proceed to Fort Bowie, Arizona Territory, and report for temporary duty not later than the 15th inst., during the absence, on leave, of Poindexter, Jefferson D., Captain and Assistant Surgeon.
- A board of medical officers, to consist of Corson, Joseph K.,
  Major and Surgeon; Havard. Valery. Major and Surgeon; and Moseley, Edward B., Major and Surgeon, is appointed
  to meet at West Point, N. Y., June 1, 1894, or as soon thereafter as practicable, for the physical examination of the
  cadets of the graduating class at the United States Military
  Academy, and such other cadets of the academy and candidates for admission thereto as may be ordered before it.
- Torney, George H., Captain and Assistant Surgeon, and Crampton, Louis W., Captain and Assistant Surgeon, will report in person to Alden, Charles H., Colonel and Assistant Surgeon General, president of the examining board appointed to meet at the office of the Surgeon General, United States Army, on Tuesday, May 8, 1894, at such time as they may be required by the board for examination as to their fitness for promotion.

- Gibson, Joseph R., Major and Surgeon, is granted leave of absence for twenty days, to take effect on being relieved from duty at Davids Island, New York.
- TEN EYCK, BENJAMIN L., First Lieutenant and Assistant Surgeon, now on temporary duty at Fort Clark, Texas, is assigned to duty at that post.
- LIPPIT, WILLIAM F., Jr., First Lieutenant and Assistant Surgeon, is relieved from duty at Camp Eagle Pass, Texas, and ordered to Fort Leavenworth, Kansas, for duty.
- Spencer, William G., Captain and Assistant Surgeon, will report in person to the president of the army retiring board at Omaha, Neb., at such time as he may designate, for examination by the board.
- WATERS, WILLIAM E., Major and Surgeon, is granted leave of absence for two months, to take effect on or about July 1, 1894.

#### Society Meetings for the Coming Week:

- MONDAY, May 21st: New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.
- Tuesday, May 22d: Connecticut Medical Society (first day— New Haven); New York Dermatological Society (annual private); Buffalo Obstetrical Society.
- WEDNRSDAY, May 23d: Connecticut Medical Society (second day); New York Pathological Society; New York Academy of Medicine (Section in Laryngology and Rhinology); New York Surgical Society; American Microscopical Society of the City of New York; Metropolitan Medical Society, New York (private); Medical Society of the County of Albany, N. Y.; Philadelphia County Medical Society.
- Thursday, May 24th: Connecticut Medical Society (third day); New York Academy of Medicine (Section in Obstetrics and Gynæcology); New York Orthopædic Society; Roxbury, Mass., Society for Medical Improvement (private); Pathological Society of Philadelphia.
- FRIDAY, May 25th: New York Clinical Society (private); New York Society of German Physicians; Yorkville Medical Association (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.
- SATURDAY, May 26th: New York Medical and Surgical Society (private).

### Letters to the Editor.

THE CONGRESSISTS AND THE ITALIAN MEDICAL PROFESSION.

PERUGIA, May 2, 1894.

To the Editor of the New York Medical Journal:

SIR: I have just read in your New York Medical Journal\* what your correspondent wrote to you about the Rome Congress, and I am quite sure that there must be some mistake on the part of your correspondent. I think that all must agree to the fact that there has been some inconvenience produced by the great number of "congressists," but this entirely depended on an incomplete organization, not perhaps adequate to the great number of medical men who came to the congress. But from these trifling things to the assertion that the "Italians were rude to the Americans and Englishmen present" there is

such a distance that I can not even conceive how it could happen to any American or Englishman who had the slightest acquaintance with our feelings to imagine that in all the congress there was only one of all Italian doctors who disliked his English or American colleagues.

I do not know if you have a correspondent here in Italy, established here for some months, but I am quite sure I tell the truth when I assert that whoever wrote to you such a thing has never been in Italy before, and has no knowledge of our feelings.

It is really a pity that the English language is not so well known in Italy as French is, and perhaps even German is. This, perhaps, may explain the little attention paid to communications made in the English language, which your correspondent thinks he noticed, what did not happen to me. I saw many gentlemen leave the room as soon as a communication was made in a language that they did not know, as I saw some Italians answer in English to English medical men. Perhaps it may be that when some persons assist to a discussion that they do not understand, they talk for some moments together. But I decidedly deny that in all the congress there was one Italian doctor who had the slightest dislike for Englishmen or for Americans, either as a nation or professionally. I wish that your correspondent would stop for some time in Italy; if that happens, I am quite sure that in a few months he would himself agree with what I assert now. In fact, the truth is that, not only medical men, but all our nation has always been extremely fond of Englishmen and Americans. This for the truth, although I am not a member of the committee of the congress, and am quite in the opposition to some ideas of those who managed all the congress. CHARLES RUATA, M. D.

#### CAMPHORATED PHENOL.

Bellport, N. Y., May 1, 1894.

To the Editor of the New York Medical Journal.

Sir: It is with some degree of gratification I note Dr. Thomas A. Elder's communication in last week's Journal on the topical application of camphorated phenol for the relief of itching and as an antiseptic in small-pox. As far as I know, I believe I was the first to call attention through the medical press to this exceedingly valuable antiseptic, as a combination, in an article which appeared in the Medical Record of August 19, 1893, entitled Bufalini's Camphorated Carbolic Acid as an Antiseptic Agent. A formula for this appears in the sixteenth edition of the United States Dispensatory, page 53, which is practically the same as noted in Dr. Elder's letter.

It is rather astonishing that a preparation backed by such an authority as Bufalini has not been more thoroughly employed in surgical and other uses where such an agent might be applicable. This can only be explained, I assume, by the fact of the wild rush of the newer antiseptics which are being constantly crowded upon our notice by enterprising commercialism and the tendency to novelty.

Since I urged its use to a larger extent on the consideration of surgeons particularly, I have employed it in the form of ointments of lard or vaseline in the proportion of one to three or four in inunctions for the acute exanthemata with the most gratifying results. In an epidemic of scarlet fever where I employed it once or twice daily in each case after bathing I found it reduce temperature and produce a sense of well-being to the patient highly gratifying. Moreover, it was efficient in preventing contagion and, I thoroughly believe, destroys the infective element in this disease when intelligently and thoroughly rubbed into the entire desquamating surface.

ment of inflammatory and parasitic skin diseases, especially those characterized by itching.

Another communication appeared in the Record of September 30, 1893, giving some account of its employment as an internal remedy in typhoid fever.

This combination is well worthy of conscientious employment, and I again unite with others who have endeavored to call attention to its exceptional and varied therapeutical properties, in the hope that it may be accepted as one of the ideal antiseptics. S. W. S. Toms, Ph. G., M. D.

### Proceedings of Societies

SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL. Meeting of April 4, 1894.

The President, Dr. FREDERICK HOLME WIGGIN, in the Chair,

Traumatic Paralysis of the Forearm and Hand .- Dr. Parker Syms presented such a case. Alfred Mitchel, sixteen years of age, a groom, had had a good family history, and had himself enjoyed perfect health. In the latter part of September, 1893, he had been kicked by a horse in the abdomen and on the posterior aspect of the right elbow. The blow on the abdomen had caused contusion and rupture of the ileum and peritonitis, for which Dr. F. H. Wiggin had operated, resecting a portion of the ileum and curing the patient. After recovering from the etherization it had been discovered that his right hand was paralyzed both as to motion and sensation. When seen by the speaker in January the patient had been in perfect health, except that he had been unable to extend the right hand or fingers. There had been a recently healed scar directly over the olecranon, but no other visible sign of injury at the elbow. His hand and forearm had been normal before the injury. It had been evident that the musculo-spiral nerve had been injured. He had been unable to extend the hand, having complete wrist-drop; when the hand was held flexed he could slightly move the fingers in extension; when the hand was held extended he could produce no extension motion in the fingers. There had been sensation throughout the hand and forearm. As sensation had been lost at the time of the injury but had returned, it had been decided to treat him expectantly. Under the use of galvanism he had slowly regained the lost function.

Extensive Cicatricial Keloids,-Dr. PARKER SYMS also presented a patient with this condition: Charles C., colored, twenty-seven years of age, had been admitted to the Colored Hospital in January, 1894. His family history had been negative, and his general health good. Six years ago the patient had entered this hospital suffering from extensive tubercular disease of the lymphatics on the right side of the neck. The speaker had operated, removing the diseased glands and fascia. Three years later there had been a similar condition on the opposite side of the neck, for which another surgeon had operated. Since then he had had recurrences, and, in all, twentyseven operations, including incisions and curettings. The site of each incision was now marked by large, elevated, irregularshaped, characteristic keloids which extended beyond the actual cicatrices. The deformity in the neck was very marked.

Dr. John W. S. Gouley said that he would like to inquire from the histologists present as to the actual state of knowledge respecting these keloids.

Dr. W. R. Townsend suggested that the case of wrist-drop · I believe it has a very wide sphere of usefulness in the treat- might be benefited by the limbs being superextended on a splint.

He had seen this treatment employed by Dr. Gibney with much success in a number of cases of wrist-drop from lead paralysis.

Dr. Gouley called attention to the fact that as long ago as 1854 to 1859 Dr. John P. Batchelder had published an elaborate paper on the treatment of these paralyses, especially of wrist-drop, by the use of a splint to insure extension.

Dr. John A. Wyeth said that he had seen several cases of paralysis of the musculo-spiral nerve after fracture in which the callus had been thrown around this nerve, causing it to atrophy. In one case, chiseling away the callus had restored the muscles to their full function after some time; in another case the nerve had been resected, but as it was a hospital case the subsequent history had not been obtained. He knew about still another case where the nerve had been united, and yet over twelve months had passed before there had been any evidence of restoration of function of the nerve, although ultimately it had been completely restored. In the case just presented he thought one could wait with advantage to see whether the functions would not be restored without operation.

Dr. Syms said that he had considered the advisability of operating in the first case, but as sensation had been partially restored when he had first seen the man he had felt that it was much better to wait. Again, the only guide to the site of the injury had been a scar over the olecranon. He had seen a number of cases of traumatic paralysis of the musculo-spiral nerve recover spontaneously, and cases of transient paralysis from pressure were not at all uncommon.

He had long hoped for further information on the subject of these keloid growths. All that seemed to be known was that they consisted of a mass of dense fibrous tissue. The ætiology was shrouded in obscurity. The speaker recalled one very marked case in which a keloid growth had indicated the former site of numerous acne pustules. He thought that many observers were inclined now to do away with the classification into idiopathic and traumatic keloid, the opinion being that all of these keloids probably resulted from traumatism.

Floating Kidney .- Dr. WILLIAM E. STUDDIFORD presented a woman, thirty-five years of age, who had given a history of syphilitic infection many years ago. She had been treated for this, and had been in fairly good health up to 1886, except for attacks of pain in the left side of the abdomen. Her weight at this time had been from a hundred and forty to a hundred and fifty pounds. In 1886 she had begun to lose flesh and strength, and had become quite nervous. This nervousness had increased up to two years ago when she had noticed that during the menstrual period the nervousness was still more aggravated, and that there was some difficulty in walking. This unsteadiness of gait had been constant for the last fifteen months. She had also complained of a dragging pain in the lower part of the abdomen on the left side, increased by stooping or lifting, and of frequent and painful micturition. These latter symptoms had become so much more severe a few months ago that she had applied at the Outdoor Department of Bellevue Hospital for treatment. At that time there had been a marked ataxic gait and a loss of patellar reflex; she had been unable to stand with the eyes closed and the feet together; there had been disturbance of vision, and pain in the back and left side. Examination had shown no disease of the uterus or its appendages, but in the left iliac fossa there had been a tender point and a movable tumor. The tumor could easily be placed in the position of the kidney, and this organ had been absent from its usual position. The tumor had therefore been diagnosticated as a movable kidney, and had been retained in place by an ordinary obstetric binder. While it was so retained many of the symptoms had been improved. The other symptoms had been supposed to be due to locomotor ataxia.

Dr. J. F. Erdmann said he had been rather chary about making the diagnosis of floating kidney, as he had recently seen in the dissecting room a case in which the kidney had been in the iliac fossa over the psoas magnus, with the origin of the renal artery from the bifurcation of the aorta. Another case also, in which the kidney had been in practically the same position, had been reported to him from the Almshouse Hospital autopsy room.

Carcinomata of the Breast.—Dr. Erdmann presented the following specimens: The first specimen was a medullary carcinoma which had been removed from Mrs. E. H., thirty-eight years of age, a nurse by occupation. In 1889 she had noticed a small growth on the right breast of about the size of a filbert. It had remained about this size until October, 1893. On the morning of January 1, 1894, she had found on awakening that the right breast was very black. There were no contusions or abrasions indicating an accidental blow during the night. When first seen by the speaker the growth had been of about the size of a hen's egg. A few days later he had excised the tumor, and on cutting into the breast itself had found the milk ducts throughout filled with clotted blood. None of the axillary glands had been involved. She had made an excellent recovery.

The second specimen was that of a carcinoma of about five months' growth, undergoing calcareous degeneration. The patient was a woman, thirty-five years of age, who had had a number of children in rapid succession. Five months and a half ago she had first noticed a small growth in the left breast. This had increased rapidly, but had been accompanied by but little pain. Subsequently, a secondary growth had been noticed. The breast had been excised along with the whole chain of axillary glands, which were diseased. One of them, of the size of a duck-sbot, on being examined, had shown marked carcinomatous infiltration.

Epithelioma of the Rectum.—A third specimen had been removed by operation from a woman, forty-four years of age, who had given no history bearing upon the rectal trouble, except that five weeks previous to the speaker's having seen her she was said to have been operated upon for hæmorrhoids. He had first seen her on June 27th, and on the next day had removed three inches and a half of the bowel, including two thirds of its circumference. The operation which he had performed was that described by Kelsey as Allingham's operation, and had consisted in passing a knife into the anus posteriorly and cutting to the tip of the coccyx, then liberating the gut with a circular incision, and pulling down the bowel-practically a Kocher operation without the removal of the coccyx. There had been no cachexia, no enlargement in the groin, and no evidence of abdominal involvement. Seven weeks after this she had noticed some trouble with the rectum, and a week later had returned with a growth of half the size of the first one. 'Two inches and a half of the rectum and about two inches square of the posterior vaginal wall had been removed. There had been no return of the growth, and the patient had gained thirty or forty pounds in weight.

Dr. Parker Syms said he had had considerable experience with such cases of rectal disease, and he thought ordinarily the operation was not sufficiently complete. The higher posteriro operation, after Kraske's method, removing sufficient bone to gain free access to the rectum was the better operation in his opinion. In this operation, one was able to remove much lymphatic tissue which could not be otherwise reached. One of his patients of this class had died of pneumonia six years after the operation and without any evidence of a recurrence of the disease.

Dr. WYETH asked about the control over the discharge of fæces.

Dr. Erdmann replied that the object had been to retain as much of the sphincter as possible in the first operation, but no effort had been made in this direction in the second operation. As a result of cicatricial contraction, and by rebuilding the perimeum as much as possible, the patient had very fair control of the feees.

Dr. WYETH said that in such cases he thought that greater control over the fæces could be secured by adopting Dr. Gerster's plan of twisting the bowel one turn upon itself.

Fibroma of the Uterus; Abdominal Hysterectomy.— The fourth specimen was that of a fibroid of the uterus, weighing three pounds eight ounces, which had been removed from an idiotic colored woman, thirty-eight years of age. The operation had been done on account of very profuse menstrual hemorrhages. The uterus had been removed by what Dr. Edebohls called pan-hysterectomy. The patient had been discharged on the twentieth day.

Epithelioma of the Floor of the Mouth.—The next specimen had been taken from O. C., a man sixty-four years of age. One uncle had had a so-called "smoker's cancer" of the lip, otherwise the family history had been negative. On August 6, 1893, a physician had told him that he had cancer. He had been referred to Dr. Joseph D. Bryant and had then come under the speaker's observation. Dr. Biggs had examined a specimen of it and had reported it to be an epithelioma. The left half of the inferior maxilla, the mucous membrane on the side of the tongue, a considerable area of the cheek, and a portion of the pillars of the fauces and of the antero-lateral wall of the pharynx had been removed about eight months ago. There had been no evidence of recurrence since then.

(To be concluded.)

#### COLLEGE OF PHYSICIANS OF PHILADELPHIA.

SURGICAL SECTION.

Meeting of March 9, 1894.

Dr. John B. Roberts in the Chair.

An Operation for an Old Dislocation of the Elbow and a Bridge of Callus between the Radius and the Ulna.—The Chairman showed a patient who had had an old dislocation of the elbow, which had occurred two years ago, and was the result of a fall from a carriage which was overturned. The injury was evidently a backward dislocation of both bones of the forearm, with compound fracture of the radius at the junction of the upper and middle thirds. When she had come under the speaker's care at the Woman's Hospital she had the right arm rigidly extended with no motion at the elbow; suffered with pain and numbness in the fingers at the ulnar side of the hand, due to pressure on the ulnar nerve, and had a suppurating sinus at a point of depression shown in the cast made of the arm before operation.

It had seemed to the speaker that it was proper to attempt to treat the old dislocation, although of two years' standing, by making a resection in order to get the arm in a flexed position. He cut down upon the olecranon, and found that the head of the radius and the olecranon was soldered by callus to the humerus in the abnormal position. The ulnar nerve was displaced and in a condition of tension. He was compelled to chisel the radius and ulna loose and cut off the triceps tendon in order to put the bones at the elbow in the position of flexion, which would be so much more useful and convenient, even if the elbow was immovable. In order to unite the triceps tendon to the ulna after flexing the joint, he was obliged to lengthen it by cutting a V-shaped flap out of the tendon. This he made with its apex upward, and then turned the flap over with its point

downward, and sutured it to the stump which had been left attached to the olecranon. He used silk sutures. He lessened the tension on the ulnar nerve by replacing it; in the course of a few days the numbness of the fingers disappeared.

In order to cover in the gape in the skin, he did an extensive plastic operation by dissecting a flap from the forearm. Her arm was then flexed at a right angle, and in the course of perhaps two months there was a considerable degree of motion. The radius and ulna were still united at the seat of the sinus by a bridge of callus, which prevented pronation and supination. He therefore determined to cut down and chisel out the bridge of bone and see if he could establish pronation and supination. Upon cutting down he found a sequestrum due to necrosis of the radius at the point of fracture. He chiseled away a considerable amount of bone and took out the dead portion of the radius. Knowing that the head of the radius would not be likely to rotate, as it had no cartilage upon it, he determined to make an artificial joint in order to get some pronation and supination in addition to the amount of flexion already obtained at the elbow. He excised three quarters of an inch of the radius, and then encouraged the girl, after he had removed the portion of bone and the wound had partly healed, to make motions of rotation of the hand.

She obtained a certain amount of passive supination and pronation, and the fingers became more flexible. During endeavors at making passive extension and flexion of the elbow, fracture of the ulna took place, some weeks later, in the upper third of the shaft. This necessitated putting her arm in a splint and prevented further massage and other motions to get motion at the elbow and wrist. As the elbow would probably become stiff, he, in order to get the hand more toward the face, allowed the fragments to unite with a little angularity. There was now a bend or angular deformity to be seen at the seat of fracture, which enabled her to bring the hand nearer the mouth than otherwise would have been possible. The wound had not entirely healed. She had lost nearly all the flexion and extension she had had from the first operation during immobilization of the joint for repair of the fracture of the ulna. She had a little motion at the elbow, not enough to be useful; there was practically no supination or pronation of the hand, but the numbness of the fingers was gone, and she could bend her fingers, which had been stiff, pretty well. She had, and had had, good motion at the wrist. Not much had been gained, therefore, except the right-angle position of the elbow, motion of the fingers, and freedom from pain and numbness. If fracture had not taken place he thought he would have obtained considerable motion at the elbow and have been able to maintain the false joint at the point of radial resection so as to give her some rotation of the hand.

The case was interesting because of the lengthening of the tendon of the triceps, the attempt to establish a point of motion in the shaft of the radius, when the head was adherent by ankylosis to the humerus, and the ease with which bridges of callus uniting the radius and ulna could be removed.

Delayed Union in Fracture.—Dr. T. G. Mobron said that in these days of antiseptic surgery we were perhaps a little too hasty in regard to the treatment of delayed union in fractures, and did not give Nature time to effect repair. The length of time taken for repair was unusually long, yet the result in two cases reported as follows had been perfect:

Case I. Delayed Union in a Fracture of the Femur.—This case had occurred in the practice of Dr. W. H. Shipps, of Bordentown, N. J. On January 20, 1893, L. M., a young woman, seventeen years of age, while coasting was violently thrown from a sled, sustaining a fracture of the right femur at about the junction of its middle and lower third. She was at once

carried to her home, placed upon a firm mattress and sand bags, and extension by weight and pulley employed. The patient, an intelligent girl, recognized from the start the importance of keeping the fragments in position, and labored in every possible way to avoid disturbance of the limb; so determined was she in this respect that she avoided, in so far as possible, a regular evacuation of the bowels, although assured of the folly of such a course. As she had a most capricious appetite, it was difficult for the first six weeks to get her to take a sufficient quantity of nourishment, although the necessity for this important aid in bone repair was constantly urged upon her. At the end of four weeks the dressings were removed and the limb was carefully inspected. No shortening was detected, but no attempt at union had taken place, notwithstanding the parts were in perfect apposition. The dressings were carefully reapplied. On March 20th, two months after the injury, an examination showed entire absence of bony union. At this juncture Dr. Shipps had requested the speaker to see the case with him. It was agreed to resort to daily massage of the entire limb, especially in the vicinity of the fracture, and to lessen the amount of extension. The limb was also incased in a firm dressing made of two Russia felt splints; a posterior one, extending from the great trochanter to within six inches of the ankle, and an anterior, extending the entire length of the thigh, firmly held in place by a roller bandage. Four weeks later the patient was allowed to get out of bed daily and walk about on crutches, care being taken that no weight was borne upon the limb. This plan of treatment was faithfully carried out, and the patient's appetite in the meantime materially improved. In the course of three weeks the circumference of the limb had visibly increased and an evident attempt at bony union was noticed. From this on the limb gradually improved in size and strength, until, at the end of eight weeks from the commencement of massage, at which time the speaker had again seen the case, consolidation was complete. The dressings were continued for a few weeks longer, when a single roller bandage took the place of splints. Careful measurement of the two limbs at this time failed to show any appreciable shortening. Altogether the patient had made a most satisfactory recovery.

Case II. Delayed Union in Fracture of the Leg .- On August 1, 1893, Captain A. S., aged fifty-one years, while at Ivigtut, South Greenland, in command of his vessel, received an injury to the right leg by the fall of a bulkhead or partition which separated the cargo of kryolite from the ballast. A medical man from the shore who was summoned, found the left leg seriously crushed and an oblique fracture of both bones about the junction of the middle and lower thirds. He applied temporary pasteboard splints, and the patient was hoisted from the hold. Four days later, bandages, pasteboard splints, and a plaster dressing were applied. Three weeks later the swelling of the limb had so subsided that he observed not only a considerable movement, but a grating of the bone. Six weeks subsequent to the injury the dressing was removed, when it was found that there was little if any union. A posterior board splint was applied, and two weeks later he left Greenland and arrived in Philadelphia on October 17th, seventy-eight days after the accident; he then entered the Pennsylvania Hospital. His general condition was good. The limb was greatly swollen, and the skin dry and rough; evidently no attention had been given to the condition of the circulation, for the limb had not been out of splints for many weeks, and had not been bathed since the accident. There was little if any effort at repair in the fracture. Attention was first directed to improving the circulation of the limb by soaking in warm water and massage. A fracture box, subsequently Russia felt splints, and finally a brace were applied. He was discharged on December 11, 1893, with considerable union, which was not firm until the close of January, when he was able to walk without any support.

Dr. G. G. Davis thought this was a good example of how plaster dressings did not keep a limb quiet. Inasmuch as they were used for that specific purpose, he thought it worth while to call attention to the fact that, at least in the way they were often applied, with a layer of cotton beneath, they were apt to permit motion at the seat of fracture. Of course, this man had had some dressing beneath the plaster bandage, which had probably been the cause of its getting loose. He would like to ask Dr. Morton whether in cases of delayed union he kept the parts absolutely quiet, or whether he considered it best to allow some motion. From the cases reported it was evident that they could be cured both by permitting motion and by keeping them at rest.

Dr. Morton would keep them absolutely quiet until the probability of repair through quiet seemed doubtful; then he would put the limb into a movable apparatus.

Rubber-Tissue Gloves for Protecting the Hands during Operations, etc .- Dr. Morton called attention to thin rubber gloves for general surgical purposes and for handling strong solutions. He had found these rubber-tissue gloves extremely useful in handling offensive cases. With them it became a pleasure to make rectal examinations, because the skin of the hands did not become saturated with fætor, and it was wonderful how many more examinations one made. Also in handling strong solutions, or even in operating in septic cases, they had an excellent field. The rubber was so very thin that it interfered very little with the tactile sense. As a rule, they went on with great ease and came off readily. He thought them of great value when handling morbid growths or making postmortems where it was possible to be inoculated. They bore steam sterilization and soaking in strong solutions of carbolic acid or bichloride of mercury.

### Book Hotices.

Pyogenic Infective Diseases of the Brain and Spinal Cord.

Meningitis. Abscess of Brain. Infective Sinus Thrombosis.

By William Macewen, M. D., Glasgow. New York: Macmillan & Co., 1893. Pp. xxiv-354. [Price, \$6.]

While it is true, as the author states, that pyogenic infective diseases of the cerebro-spinal system have only during recent years been appreciated fully, and it is also true that our knowledge regarding them is still imperfect, it will require but a few more such works as this to give us certain and accurate data that will substitute knowledge for ignorance. As it is a fact that a large number of the cases of pyogenic affections of the brain arise from neglected otitis media, it is also a fact that they should be regarded as preventable diseases.

In this volume a chapter is devoted to the consideration of the surgical anatomy of the temporal bone and of the frontal sinuses, and to the venous supply of the head.

The second chapter treats of the pathology of cerebral abscess and meningitis, because the one so frequently accompanies the other. The author believes that in the great majority of cases, if not in all, the inflammation is due to microorganisms. These find an excellent incubating chamber in the middle ear, which they usually enter through the Eustachian tube. While acute processes seldom spread into the interior of the skull, because the mucous membrane of the middle ear is still intact and the underlying bone is unaffected, yet in chronic

cases the bone is frequently necrosed and the mucous membrane destroyed. When this osseous erosion exposes the dura mater this membrane throws out a mass of granulation tissue from its external surface that obstructs the further inroads of the pathogenic process and assists in the absorption of the disintegrating bone. Dr. Macewen therefore urges that great caution should be exercised in removing masses of granulation tissue from the middle ear, because it may result in meningitis or cerebral abscess.

The third chapter treats of the symptoms of abscess of the brain, the course of which is divided into three stages: The initiatory stage, varying from twelve hours to a week, in which there are pain, vomiting, rigors, temperature, and a cessation of pus from the middle ear; the second stage, in which there are slow cerebration, a tendency to doze, slow pulse and respiration, anorexia, vomiting, paralysis, rigors, and optic neuritis; and the third or terminal stage, in which there are stupor or coma, symptoms of acute leptomeningitis, or bursting, encapsulation, or absorption of the abscess. The author states that he has found it possible to elicit a distinctive cranial percussion note as an aid to diagnosis in certain gross changes of the intracranial contents. This is caused by the note being modified by the consistence and volume of the contents and their relative position to the bone. A thin cranium vibrates more easily than a thick one. The sign is most useful in determining ventricular distention.

The fourth chapter is devoted to thrombosis of the intracranial sinuses. Two forms are recognized: the primary, or marasmic, and the secondary, or infective. The former chiefly affects the azygous sinuses, its clot tends to organize or be absorbed, there is a tendency to produce brain softening, purulent infection is seldom a sequence, and there is no accompanying leptomeningitis or cerebral or cerebellar abscess; while the infective thrombosis chiefly affects the dual sinuses, its clots tend to purulent disintegration, it does not tend to brain softening, septic or infective emboli are common, and it is often coincident with purulent leptomeningitis or with cerebral or cerebellar abscess. The section on sigmoid-sinus thrombosis is a most valuable contribution to our literature.

In abscess of the brain, infective thrombosis of the intracranial sinuses, and leptomeningitis the first step in prophylaxis is to prevent the occurrence of primary infective foci, and the second is to eradicate them when present. Chronic otorrhœa, the author thinks, is too lightly regarded, and is considered as a mere inconvenience instead of a menace to life. All persistent purulent discharges from the middle ear ought to be regarded seriously, and the physician should not rest satisfied until the discharge is cured. The safest instrument for the purpose of exposing the antrum is the rotatory bur propelled by the surgical engine; the use of the chisel and mallet is, as we helieve, properly and justly condemned.

The author has in fifty-four cases of mastoid infective disease, extending from the middle ear and unaccompanied by intracranial lesions, ablated the antrum and mastoid cells, and cleansed the middle ear, removing therefrom cholesteatomatous accumulations, masses of granulation tissue, and the ossicles when diseased. He has never purposely opened or accidentally wounded the sigmoid sinus. The operation has enabled each of these patients to have a mass of connective tissue placed between the intracranial contents and the tympanum, forming an efficient barrier against pyogenic invasion of the middle and posterior fossæ of the skull at their most vulnerable points.

Forty-three of these patients were cured and eleven were improved. His statistics further show that seventeen cases of pyogenic pachymeningitis externa were all cured; five cases of extradural abscess were cured; six cases of pyogenic cerebral

leptomeningitis were cured; of five cases of pyogenic cerebrospinal leptomeningitis, only one was cured; of twenty-five persons with abscess of the brain, nineteen were operated on and eighteen recovered. In a total of ninety-four cases of infective intracranial lesions, seventy-four patients were subjected to operation; sixty-three of them were cured, and the total mortality was thirty-one.

The careful, precise methods followed by the author, his thorough familiarity with cerebral anatomy and surgery, and his habit of waiting for time to demonstrate the value of what he has done, make this volume the most valuable contribution, to the surgery of the brain that has appeared in several years. The illustrations are magnificent, on a par with those in his beautiful Atlas of Head Sections. This volume must be of great interest to the neurologist, the aurist, and the surgeon.

Lectures on Auto-intoxication in Disease, or Self-poisoning of the Individual. By Ch. BOUCHARD, Professor of Pathology and Therapeutics, etc., Paris. Translated, with a Preface, by Thomas Oliver, M. A., M. D., F. R. C. P., Professor of Physiology, University of Durham, etc. Philadelphia: F. A. Davis & Co., 1894. Pp. xvi-302. [Price, \$1.75.]

The increasing interest manifested by the profession regarding the important subject of self-intoxication makes the appearance of this translation of Bouchard's work an appropriate and timely addition to medical literature.

The development of physiological and pathological alkaloids in consequence of putrefactive changes in the intestinal canal plays an important part in many disease processes, and such is the influence of these alkaloids in causing a transition from an apparently normal to an evidently abnormal condition that it is more and more necessary that the physician should take them into account in the routine of his daily work. The investigations of Selmi, Brieger, Pasteur, Frankel, Hankin, Martin, and many others have succeeded in isolating these alkaloids from the serum, the urine, and the fæces, and have shown that disease may, and often does, depend upon the presence in the system of substances capable of combining with acids to form salts or bases, which substances Selmi called ptomaines. The latter, produced by the action of bacteria upon organic matter, are to be distinguished from those basic substances that result from intra-organic tissue metabolism, and are known as leucomaines. As all ptomaines are not poisonous, Brieger suggested that the term ptomaine should be restricted to non-poisonous basic products, those that are poisonous being called toxines.

In this volume the author endeavors to show that man is, by the very nature of his own metabolism, continually on the threshold of disease. Bichat said: "Life is the aggregate of the functions that resist death," and Bouchard says virtually that health is the aggregate of the functions that resist self-intoxication. The latter is only prevented by the activity of the excretory organs, chiefly the kidney.

The subject matter is arranged in thirty-two lectures, the preliminary discourses being devoted to the general features of the subject and the final lectures considering special morbid conditions. The nature of the pathogenic processes in general, and the production and elimination of poisons by the organism, precede the consideration of the methods of the experimental study of the toxicity of the products of emunction. Seven lectures are devoted to the origin and character of the toxic substances in the urine, and five to the pathogenesis of uramia. Three chapters are devoted to ordinary gastro-intestinal self-intoxications, four chapters to the self-intoxication of typhoid fever, two chapters to hepatic self-intoxication, and three chapters to the self-intoxication, and three chapters to the self-intoxication of cholers.

The translator has succeeded admirably in preserving the author's agreeable and interesting style, and the volume deserves a wide popularity.

A Manual of Nursing in Pelvic Surgery. By Lewis S. Me-Murthy, A. M., M. D., Professor of Gynaecology in the Hospital College of Medicine, Louisville, Ky. Louisville: John P. Morton & Company, 1894. Pp. 6-7 to 92.

The author states that this little book is an elaboration of the "working notes" he prepared for the use of the nurses at the Jennie Casseday Infirmary for Women. It is a complete and practical guide for nurses engaged in the care of women with surgical diseases peculiar to their sex, and it is written in a clear manner that makes its teachings easily understood.

A Text-book on Discuses of the Eye. By Henry D. Noyes, A. M., M. D., Professor of Ophthalmology and Otology in Bellevue Hospital Medical College, etc. Second and Revised Edition. Illustrated by Five Chromo-lithographic Plates, Ten Plates in Black and Colors, and Two Hundred and Sixty-nine Wood Engravings. New York: William Wood & Co., 1894. Pp. xvii-816.

This work needs no fresh introduction to the profession, who well know its admirable character. The same arrangement prevails as in the first edition, but a number of additions have been made. Considerable space has been devoted to cerebral anatomy and physiology, and a number of chapters have been rewritten so as to set forth the most recent well-established views in ophthalmology. Many changes have been made in the illustrations and new ones have been added. The work is a worthy memorial of its author's untring industry.

The International Medical Annual and Practitioner's Index:
A Work of Reference for Medical Practitioners. By various contributors, 1894. Twelfth Year. New York: E. B. Treat & Co. Pp. 704. [Price, \$2.75.]

If we say that the International Medical Annual for 1894 ably maintains the standard of excellence set by its predecessors of the past eleven years, we do it but justice and at the same time pay it a-compliment than which there can scarcely be a better. And yet the constant endeavor of its editors to improve upon it each year results in giving us an annual a little more valuable and a little more complete.

This year we may note as a distinct improvement the many illustrations (some of them, it is true, very bad, but most of them excellent) and, especially of interest, those accompanying the chapter on insanity.

Of yet more value, however, is the care shown in presenting the reports of more than one authority upon many of the more important subjects, a care which is rewarded by a singular freedom of the volume from unrestricted opinion and prejudice. To this absence of narrowness we called attention in reviewing the volume in 1893, and we are pleased to note the growth of that impartiality and liberality in the volume for 1894.

The Human Element in Sex. Being a Medical Inquiry into the Relation of Sexual Physiology to Christian Morality. By Dr. Elizabeth Blackwell. New Edition. London: J. & A. Churchill, 1894.

The authoress's purpose in the present work is to aid in the instruction of parents and guardians of the young, from the standpoint of what she designates as the Christian physiologist, in the various features of the sexual functions. This edition of a work published ten years ago contains but little essentially

new. It seems to us somewhat too elaborate to accomplish its intended purpose with the average reader, but its plan and purpose can not but meet with the approval of every thoughtful physician.

#### BOOKS, ETC., RECEIVED.

Essentials of Anatomy, including the Anatomy of the Viscera, arranged in the form of Questions and Answers prepared especially for Students of Medicine. By Charles B. Nancrede, M. D., Professor of Surgery and Clinical Surgery in the University of Michigan, Ann Arbor, etc. Fifth Edition. With an Appendix on the Osteology of the Human Body; the whole based on the Last Edition of Gray's Anatomy. One Hundred and Eighty Fine Illustrations. Philadelphia: W. B. Saunders, 1894. Pp. x-17. to 388. [Price, \$1.] [Saunders's Question Compends.]

Weekly Abstract of Sanitary Reports issued by the Supervising Surgeon General of the Marine-Hospital Service. Vol. VIII. (Nos. 1 to 52.)

Transactions of the New York State Medical Association for the Year 1893, Vol. X.

A Retrospect of Surgery. January, 1890, to January, 1894. By Francis J. Shepherd, M. D. [Reprinted from the *Montreal Medical Journal*.]

The Aseptic Dressing of the Umbilical Stump. By Joseph Eve Allen, M. D., Augusta, Ga. [Reprinted from the American Journal of Obstatrics.]

Three Illustrative Cases of Abdominal Section. By Augustus Schachner, M. D., Louisville, Ky. [Reprinted from the American Journal of Obstetrics.]

Further Remarks on the Occurrence of a Form of Non-albuminous Nephritis other than Typical Fibroid Kidney. By D. D. Stewart, M. D., Philadelphia. [Reprinted from the *Medical News*.]

Traitement chirurgical de la phtisie laryngée. Par le Dr. Gonguenheim. [Extrait des Annales des maladies de l'oreille et du larynx.]

Grundriss der Kinderheilkunde mit besonderer Berücksichtigung der Diätetik. Von Dr. Otto Hauser, Assistent der Universitäts-Kinder-Poliklinik in der kgl. Charité zu Berlin. H. Konnfeld, 1894. Pp. xii-318. [Preis, Mark 7.]

Thirty-third Annual Report of the Cincinnati Hospital to the Mayor of Cincinnati for the Fiscal Year ending December 31, 1893.

Food Products. 1. Twelve Edible Mushrooms of the United States, with Directions for their Identification and their Preparation as Food. By Thomas Taylor, M. D. United States Department of Agriculture. Division of Microscopy.

The New Orleans Sewerage System. Inaugurated Wednesday, April 18, 1894. [Reprinted from the New Orleans Times-Democrat.]

Essentials of Nervous Diseases and Insanity: their Symptoms and Treatment. A Manual for Students and Practitioners. By John C. Shaw, M. D., Clinical Professor of Diseases of the Mind and Nervous System, Long Island College Hospital Medical School, etc. Second Edition, revised. Forty-eight Original Illustrations, mostly selected from the Author's Private Practice. Philadelphia: W. B. Saunders, 1894. Pp. x-17 to 194. [Saunders's Question Compends, No. 21.] [Price, \$1.]

Practical Lectures in Dermatology. Comprising a Course of Fifteen Lectures delivered at the University of Vermont Medical Department during the Session of 1892 and 1893. By Condict W. Cutler, M. S., M. D., Professor of Dermatology, University of Vermont, Physician in Chief and Dermatologist to the New York Dispensary, etc. New York and London: G. P. Putnam's Sons, 1894. Pp. viii-233. [Price, \$2.]

## Miscellany.

The Cutaneous Absorption of Guaiacol.—The Union médicale for April 1st contains an account of a communication to the Société des sciences médicales, by M. G. Linossier and M. M. Lannois, on the lowering of the temperature produced by painting and injecting with guaiacol. With subcutaneous injections of relatively feeble quantities of guaiacol, a lowering of the temperature had been obtained comparable to that produced by painting with it.. The authors had used a mixture of equal parts of oil of sweet almonds and guaiacol. After injecting the contents of an ordinary syringe containing a cubic centimetre, the temperature had fallen two degrees. In one of their patients the temperature had been lowered from 102.1° to 95.5° F.; there had been chills and signs of collapse. In these conditions, the thermic lowering was proportional to the quantity of guaiacol introduced under the skin. In the same patient a syringeful of the mixture had lowered the temperature from 101.5° to 97.7°, and half a syringeful from 101.6° to 99.3°. In another patient, a syringeful had lowered the temperature from 102.5° to 100°, and half the quantity from 103.1° to 101.8°. This was a strong argument in favor of the cutaneous absorption of guaiacol; but the demonstration was not complete; it had only been proved that the absorbed guaiacol acted in the same way as that applied on the skin. The authors, struck with the intensity of the cutaneous absorption in their first experiments, thought it would be of interest to point out the mechanism and the conditions. They related the following cases: A napkin, impregnated with guaiacol, was held from ten in the morning until four in the afternoon before the mouth of a young patient convalescent from typhoid fever, who showed very marked thermic elevations in connection with subcutaneous abscesses. At the end of that time, the urine contained only 0.1 in 1,000 of guaiacol. Several days afterward the right thigh was painted with thirty grains of guaiacol, many precautions being taken to prevent pulmonary absorption, and the painted part immediately covered with an impermeable fabric. During this time the patient breathed behind a screen. Six hours after the painting, the urine showed 0.9 in 1,000 of guaicol, and the temperature had fallen two degrees. In this case the pulmonary absorption had been exaggerated, and 0.1 in 1,000 of guaiacol had been found in the urine, whereas, after the painting, the proportion had been nine times as great, and, in the meantime, the absorption by the respiratory ducts had been reduced to a minimum, if not to zero. The slight importance of pulmonary absorption is shown in the fact that inhalations of guaiacol do not lower the temperature of tuberculous-fever patients. In the second case the chest of the patient was painted with thirty grains of guaiacol and then carefully covered for five hours. During the whole time the patient breathed outside of the room by means of a rubber tube, and four hours afterward the urine showed 2.8 in 1,000 of guaiacol, and nine hours afterward, 3.3 in 1,000.

The cutaneous absorption of guaiacol thus proved beyond a doubt, there remained only the mechanism to establish. The guaiacol may have been absorbed in a liquid state by the unbroken skin, or it may have exercised an alterative action on the epidermis in such a way as to render it permeable. Finally, it may be supposed that the guaiacol, which is volatile, was absorbed in a state of vapor. The progress of this absorption was regular; often after fifteen minutes the urine showed traces of guaiacol, and after half an hour several milligrammes were invariably found. During an hour and a half the proportion was increased little by little, and attained its maximum in between

an hour and a half and four hours. In from five to seven hours there was a considerable decrease. By this time half the guaiacol had already passed into the urine, and the other part was eliminated with the rest of the urine in the twenty-four hours. On the following day the urine often did not contain more than a trace of guaiacol. The total quantity eliminated was always a considerable fraction of the guaiacol deposited on the skin. Among the conditions which went to vary the total quantity eliminated, the most important was the dose. The  $\varepsilon x$ -tent of surface painted had also its importance. In the same patient thirty grains were painted first on a surface of a hundred and eighty square centimetres, and afterward on three hundred square centimetres. In the first case, after three hours, the urine contained nine grains of guaiacol, and in the second, after two hours, thirty-three grains in 1,000.

Absorption seemed to be more rapid on the thorax than on the limbs; in this respect, certain conditions also must be taken into account, such as age, sex, nature of the skin, etc. After repeated experiments the authors have come to the following conclusions: 1. Guaiacol applied by painting is absorbed by the skin, and this absorption is produced, at least in a great measure, by its vaporous state. 2. The absorption is very rapid; fifteen minutes after painting, the medicament may be detected in the urine. During an hour and a half the proportion increases little by little, and attains its maximum in from an hour and a half to four hours. The elimination is nearly complete in twenty-four hours. 3. After twenty-four hours the total quantity of 55.5 per cent. of guaiacol may be found, after the skin has been painted with from thirty to sixty grains of guaiacol. The absolute quantity found in the urine has been as much as thirty-two grains after an application of sixty grains, and fifty grains after an application of a hundred and fifty grains. 4. Cutaneous absorption is such then that it permits of saturating the organism without recourse to the digestive or subcutaneous routes.

A New Sign of Lead Poisoning.—In the Presse médicale for April 21st there is a summary of an article by M. E. Destrée, published in the Journal de médecine de Bruxelles. In eighteen out of twenty persons affected with lead poisoning the author has observed a narrow zone of hyperæsthesia at the level of the articulation of the manubrium with the ensiform cartilage. As a general rule, pressure on the sternum is really painful only under one of two conditions-namely, when the bone is diseased, as is the case in leucocythæmia with lesions of the bone marrow, or when the thoracic wall and the skin are hyperæsthetic, as happens in hysteria, sometimes in neurasthenia, and often in chronic alcoholism. But in these latter cases the hyperæsthesia is not found to be so limited in extent as it is in lead poisoning. Saturnine hyperæsthesia is indeed a symptom of nervous origin, comparable to the intercostal neuralgias observed by Rosenthal. There is nothing astonishing, says the author, in the fact that the sternal hyperæsthesia is so precisely marked when we remember that Beau has shown that there is never any anæsthesia at the level of the scrobiculus cordis in lead poisoning, and that in lead colic there is very decided hyperæsthesia of the abdominal wall.

Reflex Contraction of the Adductors of the Thigh on Percussion of the Opposite Patellar Tendon.—At a recent meeting of the Société médicale des hôpitaux, a report of which is published in the Union médicale for April 17th, M. Marie related the case of a young man who had been attacked with myelosyringosis in a pseudo-acromegalic form, and showed how the patellar reflex acted. This reflex was exaggerated on the right and abolished on the left. This curious difference was seen not only in myelosyringosis, but also in tabes and in gen-

eral paralysis. If the left patellar tendon was struck, no movement of extension was produced, but a very distinct movement of adduction of the thigh by contraction of the adductors was observed. So, if the patellar reflex was absent in the patient, it was not in consequence of an alteration of the centripetal routes, but of one of the motor center, although, while the patient was walking, the left leg worked well and no atrophy of the femoral triceps was noticed. There are certain authors, says M. Marie, notably in England, who maintain that the phenomena referred to (tendinous reflexes) are not reflexes; that the muscular contraction which constitutes them is determined by a direct excitation, not reflex, of the muscular fibers, under the influence of the shock which is communicated to these fibers by the percussion of the tendons. In the case related by M. Marie the reflex nature of the contraction of the adductors of the right thigh could not be denied. This contralateral contraction of the adductors of the thigh is seen, moreover, in a large number of healthy subjects in whom the patellar reflexes are normal. This phenomenon may have a great clinical importance, as it permits of distinguishing in certain cases if the absence of the patellar reflex is due or not to an alteration of the centripetal paths, and if it has to do with a medullary affection or an alteration of the peripheral nerves.

This symptom is all the more important as the objective signs warranting the making of a diagnosis are almost wholly wanting.

The Proper Direction of the Great Toe .- At a recent meeting of the Paris Société de biologie, a report of which appears in the Progrès médical for April 21st, M. Félix Regnault presented an abstract of an essay of his which is to appear complete in the proceedings of the Société d'anthropologie. The direction of the great toe, according to M. Regnault, varies according to the way in which the foot is managed. Persons who habitually hold objects between the first and second toes have the great toe pointing inward in relation to the axis of the body. Narrow shoes, on the contrary, push the great toe outward. In persons who go barefooted and use their feet only for walking anthropologists and physicians are agreed, up to the present time, that the great toe and the inner border of the foot form a straight line. Meyer was the first to maintain this proposition, and he recommended a form of shoe, the so-called "rational" shoe, square at the toe and with the inner border forming a straight line. Quite recently Meyer's position has been sustained by Pestal, Stourke, Ziegler, Manouvrier, and Blum. It is true that Brundt and von Lindau detected an error in Meyer's observations, and pointed out that the axis of the foot passed through the second toe and not through the first, as Meyer maintained, but the question of the axis of the great toe remains settled. From numerous examinations it has been ascertained that in persons who have never worn shoes the great toe is in a state of slight adduction (the abduction of the French). Of thirty-six natives of Dahomey, who use the foot as a prehensile organ, sixteen had the great toe pointing inward, six had it pointing straight forward, and fourteen had it directed outward. A few little barefooted children observed at Kehl showed slight adduction. Finally, numerous photographs preserved by the Société de géographie show how frequent this adduction is among peoples that use their feet as prehensile organs and go barefooted. Meyer's error came from his having made his examinations on the newborn, in whom the great toe is really parallel with the axis of the foot, but in whom, as soon as they begin to walk, it is directed a little outward. It results from this that the rectilinear inner border of the so-called "rational" shoe is in reality defective. All races have employed shoes with the inner border a little convex; this is to be seen in the

foot-gear of the Chinese and of the ancient Greeks, Romans, Gauls, and others. The important thing is not to exaggerate this curve in accordance with the demands of fashion.

The Ophthalmoscope in Meningitis. - As the deeper structures of the eye have a direct communication with the arachnoid space of the brain and spinal cord, through the intervaginal space, it is evident that a systematic examination of the fundus of the eye with the ophthalmoscope will often reveal the condition of the meninges and indicate the extent to which the nerves are involved. In clinically studying forty cases of cerebro-spinal meningitis, with special reference to the derangements of the eyes, Dr. R. L. Randolph (Johns Hopkins Hospital Bulletin) has examined thirty-five patients with the ophthalmoscope, and found the fundus of the eye normal in only seven cases, the optic disc usually being congested, with the retinal veins distended and remarkably tortuous. In only three of the seven cases was the entire eye in a normal condition, and in these three the patients recovered. Of the four fatal cases with normal fundus, in one the patient had divergent strabismus and dilated pupils, another patient had marked nystagmus, another had greatly dilated pupils, and one was examined early in the disease. Many epidemics of cerebro-spinal meningitis have been noticed to have one or more eye symptoms in common, the most frequent being conjunctivitis and changes in the pupils. A special type of eye affection, however, is apt to be peculiar to every extensive epidemic. A systematic examination of the eyes with the ophthalmoscope will be useful in all suspected cases. The mere existence of good vision does not mean a sound optic nerve or retina, for a choked disc is often found where the visual disturbances are very slight; and frequently, when other eye symptoms are absent and the general symptoms are misleading, changes in the fundus of the eye may be found which indicate the purely cerebral disturbance. In cerebro-spinal meningitis the existence of eye symptoms, especially where the fundus is involved, indicates a grave prognosis.

Acarophobia.-In the Revue générale de clinique et de thérapeutique for April 21st there is an article on this subject by M. Georges Thibierge, of which the following is the substance: Persons who are pursued by a fear of the itch constitute a class of patients very difficult to deal with, for the most peremptory medical reason often fails to convince them of the groundlessness of their fear. The acarophobic types are numerous and belong to the class of neuropathics. In these patients signs of manifest nervousness are observed. They are irritable, unstable in character, crying and laughing easily, subject to migraine or to neuralgia, and exaggerate all their sufferings; having had the disease once, they believe that it persists or will return. They are the ones most to be dreaded by the physician, as, knowing from experience the symptoms of the disease, they are more apt to deceive him in describing to him a symptomatology more or less allied to that of the itch. Often the cutaneous irritation produced by the parasite and by the external applications necessary to combat the disease remains long after the cure has been effected; a pruritus, sometimes intense and persistent, causes the patient to think that the disease has returned, and he goes at once to a physician and tells him that he has the itch. A rapid examination is very often sufficient to undeceive the doctor, who perceives symptoms of a dermatosis very different from those of the itch, notwithstanding the patient's protestations. To convince him of this is far from easy, and his obstinacy is all the harder to overcome if he is attacked with one of those generalized pruriginous affections, characterized by excoriated papules spread over various regions of the body, in which the neuropathic tendencies of the patient do not account for the intensity and the tenacity of the pruritus. It is necessary then to make a very thorough examination to ascertain if it is the itch or not, and as soon as the physician is perfectly sure of his diagnosis he must convince the patient of the fact. If there is the least reticence on his part, the patient loses confidence. Sometimes, at the end of his resources, the physician advises a new treatment, which, says M. Thibierge, should not be too severe, although of sufficient importance in the patient's eyes to impress him with its value. Applications over the whole body of an ointment of a ten-per-cent. solution of naphthol or of an ointment containing from ten to fifteen per cent, of sulphur and one per cent, of menthol should be recommended; also the applications should be preceded by a bath in which plenty of soap is to be used. It is well, moreover, to recommend keeping the ointment on for several hours, and then taking another bath in which starch has been dissolved in order to subdue the irritation produced by the ointment. Before this therapeutic measure has time to fail, the patient generally allows himself to be convinced, and consents to submit to the proper treatment for the dermatosis with which he is really attacked. Hydrotherapy, says the author, is of great advantage in this treatment, because of its favorable influence not only in a certain number of pruriginous affections, but also in the neuropathic condition of the patient.

Another class of acarophobics are those who have never had the itch, but who are in constant fear of it. Any cutaneous affection more or less pruriginous will cause them to scratch frantically, and convince them that they are attacked with the disease. These patients are nearly always neuropathies who are strengthened in their belief, partly from having come in contact with persons really suffering from the itch, and partly from the pruriginous appearance of the papules produced by their energetic scratching. The foregoing treatment, says M. Thibierge, applies also to this class of acarophobics.

There is, however, another cause for acarophobia as yet but little known; it is cocainomania. In this intoxication a particular form of delirium is observed; an hallucinatory delirium which is especially observed in cutaneous troubles. The patient experiences peculiar sensations and proceeds to pierce his skin with the point of a needle in order to extract the foreign body which he believes to be some sort of an animalcule. Some patients will affirm that their skin is filled with acari. In these cases the similarity of the hallucination should put the physician on his guard against making an error in his diagnosis. The nervous manifestations of cocainism should prove to him that it is a case of true psychopathy. At all events, says M. Thibierge, this peculiar form of pruritus constitutes such a special type in the group of affections which may simulate the itch that it is worthy of mention.

Overcrowding of the Profession in California.—We are indebted to the editor of the Oscidental Medical Times, of Sacramento, for advance proofs of its report of the recent annual meeting of the Medical Society of the State of California. From the president's address, by Dr. C. G. Kenyon, of San Francisco, we extract the following:

"As before stated, in this State we have about 2,700 practitioners of medicine and surgery, graduates of regular medicine and licentiates of its board of examiners, without counting several hundred licentiates of homœopathy and eclecticism. This vast number has as a field of labor a State with a population of 1,500,000, which by a simple process of division shows one doctor to every five hundred of population. To say that our profession is overcrowded expresses a fact too patent to admit of discussion.

"As an equal distribution leaves only this small ratio for a

clientèle, what must be the portion left to some of the profession, when we find leading physicians who enjoy the patronage of thousands? The obvious tendency of this overcrowding, it is to be feared, is to lower the standard of professional conduct among regularly educated and licensed practitioners.

"We have also to consider, in addition to this unpleasant picture of a small army of medical men striving for existence in a limited field, a host of quacks of various kinds and degrees, who, like the camp-followers that hung about Sherman's army on his famous "march to the sea," are ever on the alert to pick up choice bits of forage and sustenance that should fall to the lot of the regular soldier, whose mess must suffer to the extent of the irregular depredations. Here we have a somewhat homely but, I think, pertinent illustration of the situation.

"But it is easier to depict this unfortunate condition of affairs than to recommend measures of adequate relief. The following suggestions, however, seem to me to be appropriate: We should no longer hold out to intending students of medicine alluring pictures of the excellence of this State as a field for practice. Until the time comes, if ever, when there shall be a more reasonable proportion between practitioners and patients, it is bound to be a question of the survival of the fittest, and meanwhile only moderate encouragement should be given to students, and to those only who, by more than average ability, and by a high degree of preliminary education, give promise that at the end of their course of medical study they will come into the field fully equipped and qualified to engage in what, at best, must be a struggle for existence.

"Again, it is well known that medical men can not go from this to other countries on the American continent or in Europe and assume the practice of medicine until after a strict examination there, and the securing of a certificate in accordance with the laws of the government under which they may choose to settle. We, however, with that excess of liberality found only in this land of refuge for all people, and of the refuse of many, the 'Heathen Chinee' not excepted, receive all comers with open arms, welcome them to share our meager loaf, and our people patronize them to the exclusion, frequently, of those to the manor born, and at least equally qualified by natural ability and education. The halo of mystery and greatness which hovers about a foreign doctor seems to have a peculiar fascination for the American mind, and our imported frater is not always too modest to use this peculiar bent for all the advantage it may bring him."

The Neuralgia of the Toothless.—In the Journal des praticiens for April 23d there is an article on this subject by M. Duplay in which he remarks that this form of facial neuralgia is supposed to have its origin in the compression of the dental nervous branches by a condensing alveolar osteitis. The neuralgia of the toothless is seen also in others, for recently M. Duplay observed a case in which the attacks had recurred for seven years, and had not yielded to treatment. Any movement of the mouth produced pain. The majority of the patient's teeth had been extracted, but the neuralgia persisted, and resection of the infra-orbital nerve was done. Nine months after that the pain returned, and all the teeth of the right upper jaw were extracted, except the two incisors and the canine. The pressure had given rise to severe pains. This neuralgia, says the author, was analogous to that of the toothless; there were none of the classical Valleix's tender points, but there were pains radiating toward the ear, the neck, and the eye. Pain was produced by pressure on the alveolar border of the right upper jaw, and, finally, there was an alveolo-dental periostitis. With regard to the treatment, says M. Duplay, sulphate of quinine might be prescribed successfully if the neuralgia was

idiopathic and intermittent. Symptomatic neuralgia with a nervous lesion indicates other treatment. This is a specific reflex neuralgia having the dental lesion for its origin. Resection of the facial nerve had been done, but had given only temporary relief. Excision of Gasser's ganglion could be performed, but it was a dangerous operation, and M. Duplay preferred to attempt the resection of the alveolar border near the seat of pain, as advocated by Gross, of Philadelphia, in 1870, and advised it in the neuralgia of the toothless.

The Massachusetts Medical Society.-The treasurer, Dr. Edward J. Forster, of No. 51 Massachusetts Avenue, Boston, writes to us as follows:

A catalogue of all the fellows of the Massachusetts Medical Society from its organization in 1781 is now going through the press. If any of your readers will furnish me with any of the Christian names of past fellows, the initials of which are given in the following list, I shall esteem it a favor:

Admitte	d.	Last known address.
1856.	Barnes, Norman S.	Pittsfield,
1856.	Beals, Homer H.	Pittsfield.
1842.	Bonney, William P.	Fall River.
185	Bostwick, Elias W.	Canaan, N. Y.
1851.	Brown, Paris B.	Lowell.
1840.	Calef, Jonathan S.	San Francisco.
1851.	Church, Allen S.	Great Barrington.
1839.	Couch, John W.	Great Barrington.
1848.	Danforth, Nathaniel B.	Chatham.
1838.	DeChene, J. G. F. Miville.	Springfield.
1846.	Dickinson, Samuel F.	Pittsfield.
1855.	Durgin, Elijah S.	Boston.
1817.	Ellis, Joel E.	Augusta, Me.
1851.	Gleason, Ezra W.	Boston.
1832.	Hanaford, William G.	New York,
1841.	Hardy, Benjamin F.	California.
1855.	Kendall, Albert A.	Newton,
1849.	Malcolm, Alexander B.	Council Bluffs, Iowa.
1887.	Maynard-Bellerose, Joseph H.	Worcester.
1853.	McLaughlin, D. L.	Roxbury.
1852.	Peck, William L.	Pittsfield.
1813.	Peet, Edmund C.	New Marlboro'.
1871.	Pratt, Charles B.	Boston.
1858.	Roberts, S. O.	
1851.	Ryan, H.	
1858.	Skinner, Joseph T.	Springfield,
1857.	Smith, George C.	Haverhill.
1841.	Smith, Jonas M.	Brooklyn, N. Y.
1833.	Suow, Asa B.	Boston.
1844.	Stewart, Thomas H.	Springfield.
1834.	Sweet, Samuel B.	New York.
1862.	Tucker, Martin A.	Pittsfield.
1817.	Tyler, Platt B.	West Stockbridge.
1860.	White, Samuel E.	Springfield.
1860.	Williams, A. A. C.	Pittsfield.

How to Find the Upper End of a Severed Tendon.—In the April number of the Revue des sciences médicales there is an abstract of an article by M. Félizet, published in the Bulletin de la Société de chirurgie, on a means of finding the upper end of a divided flexor tendon of the finger. The procedure consists in complete extension of the neighboring finger or of the two adjoining fingers. In consequence of certain delicate fibrous bands passing between the flexor tendons in the great carpal sheath this brings the upper part of the wounded tendon into

North Adams.

1864. Williams, Alfred G.

Strychnine as an Antidote to Toadstool Poisoning.

maceutical journal certain brilliant results achieved by Dr. Königsdörfer in the treatment of toadstool poisoning by means of subcutaneous injections of strychnine in doses of 0.015 of a grain. The recovery is said to be sometimes instantaneous, as

The Dose of Exalgine. At a recent meeting of the Paris Académie de médecine, reported in the Mercredi médical, M. Dujardin-Beaumetz stated in reply to a question that great prudence should be exercised in the administration of exalgine, and that it was quite wise to give it in divided doses, each dose not exceeding four grains.

The late Dr. Lutkins, of Jersey City.—At a meeting of the medical profession of Jersey City, held May 11, 1894, the following preamble and resolutions were unanimously adopted:

Whereas, It has pleased the Ruler of the Universe to call from our ranks our friend and colleague, A. A. Lutkins, M. D., a zealous and able member of our profession, generous and noble as a man, as a physician skillful and wise, one who for years has gone up and down our streets night and day ministering to the sick and suffering, to which all classes will testify, ready at all times to counsel with those younger in our profession; there-

Resolved, That, while testifying to his honorable record and unostentatious labor in the interests of suffering humanity, we deeply sympathize with his bereaved family, and respectfully tender them our sincere condolence, though knowing full well that words do not truly express the respect and esteem which were accorded to our deceased friend and professional brother by all who knew him within medical circles and by the general community.

Resolved, That a copy of these resolutions be presented to his family, and that they be published in the Medical Record, the New York Medical Journal, and the Evening Journal.

THEODORE F. MORRIS, M. D., Chairman. EDWARD P. BUFFETT, M. D. [Signed.] JOSEPH F. FINN, M. D. WILLIAM PERRY WATSON, M. D., Secretary.

The New York State Medical Association .- The Fifth District Branch will hold its tenth annual meeting in Brooklyn, at No. 315 Washington Street, on Tuesday, the 22d inst., under the presidency of Dr. J. D. Rushmore, of Brooklyn, besides whose address, on The Prevention of the Disagreeable and Dangerous Symptoms produced by Ether as a General Anæsthetic, there will be a paper on The Dietetic Treatment of Consumption, by Dr. T. J. McGillicuddy; one on The Treatment of Chronic Oophoritis with Electricity, by Dr. Edward Sanders; a report of A Case of Chronic Peritonitis with Intestinal Fistula: Cœliotomy, Enterorrhaphy, Recovery, by Dr. Frederick Holme Wiggin; and a general discussion on Vaccination.

The New York Academy of Medicine.—The programme for the meeting of Thursday evening, the 17th inst., included a paper on The Nature and Management of Functional Gastric Disturbances, by Dr. Charles G. Stockton, of Buffalo; and one entitled Clinical Observations on Erosions of the Stomach, and their Treatment, by Dr. Max Einhorn.

At the next meeting of the Section in Ophthalmology and Otology, on Monday evening, the 21st inst., Dr. W. M. Leszynsky will demonstrate the technique of metallic Electrolysis in the Treatment of Trachoma; and Dr. S. M. Payne will read a paper on Regular Astigmatism.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 23d inst., Dr. Wendell C. Phillips will report The History of a Case of Thyreotomy for The Nouveaux remèdes for April 24th cites from a Russian phar- | Multiple Papillomata of the Larynx, and show the patient.

## THE NEW YORK MEDICAL JOURNAL, MAY 26, 1894.

### Original Communications.

#### SCORBUTUS IN INFANTS.\*

BY WILLIAM P. NORTHRUP, M. D.,
ADJUNCT PROFESSOR OF DISEASES OF CHILDREN
IN BELLEVIE HOSPITAL MEDICAL COLLEGE;
ATTENDING PHYSICIAN TO THE
TERIAN, FOUNDLING, WILLIAMD PAINCER, AND RIVERSIDE HOSPITALS;
CONSULTANT PHYSICIAN TO THE NEW YORK KYRANT ASTIUM,

AND FLOYD M. CRANDALL, M. D.,

SECRETARY OF THE PEDIATRIC SECTION, NEW YORK ACADEMY OF MEDICINE; LECTURER ON DISEASES OF CHILDREN, NEW YORK POLYCLINIC.

The first-mentioned writer, when he saw at the Foundling Asylum in 1889 a child suffering from scurvy, groped among several diseases for an explanation of the symptoms. No diagnosis having been made, the baby was not treated for scurvy, and, not being treated for scurvy, it died. The post mortem findings revealed the true nature of the disease. This was the first case of undoubted scorbutus in an infant recorded in the medical literature of the United States, and it is yet the only case completed by a full autopsy record. A few cases of cachexia thought to be scorbutic had been seen by Jacobi and Forchheimer, but had never found their way into indexed literature.

Two years later the writer met with a typical case in consultation. This was in rich surroundings, was instantly recognized, treated, and quickly cured. These two cases compass the entire field. One, a foundling undiagnosticated, came to autopsy, showing typical lesions. The second, early diagnosticated and promptly treated, was better in a few days, and well in a month. The first might be an institution curiosity, but the second brought the disease into the field of the general practitioner.

Being suspicious that scurvy might be of occasional occurrence in general practice, the same writer, in 1891 set about finding cases like the two in his possession. The surgeon general's office could furnish but one possible but not typical case. In New York and vicinity seven well-marked cases, by dint of search, were added to the two, also two more less definite—making a total of eleven. These eleven cases were reported in a paper read before the American Pædiatric Society in September, 1891.

The important features in the pathological anatomy of scurvy are well illustrated in the asylum case already referred to. The gums showed the characteristic signs of hæmorrhagic gingivitis, being dark, spongy, and bloody. The main interest otherwise lay in the condition of the legs. The left thigh was symmetrically enlarged, but both thighs were above normal in size. The femur was normal at its upper extremity. The lower half was invested with a black, grumous, subperiosteal layer of blood. The lower epiphysis was detached and the lower end of the shaft macerated, eroded, and soft, lying loose in the black, disintegrating blood-clot. The tibiæ were surrounded by thin, dark, hæmorrhagic layers beneath the periosteum, and the proximal portions of both were congested. The fibulæ

and the bones of the upper extremities were normal. The accompanying illustration was drawn from a specimen which consisted of a lateral half of the lower limb of the less affected side. Microscopical examination of the bone disclosed no syphilitic or rhachitic changes, and no inflammatory changes in bone or periosteum. The softened, macerated bone gave no evidence of suppuration, but there was moderate congestion of the femur and the upper extremity of the tibia.

All the lesions of scurvy are hæmorrhagic in character, due probably to diapedesis. The most characteristic are sub-

periosteal hæmorrhages, chiefly of the long bones. The femora are most commonly affected and there is a tendency to separation of the epiphyses. Hæmorrhages into the mucous surfaces are usually present, the gums being chiefly affected, presenting a condition to which the term hæmorrhagic gingivitis may be appropriately applied. Deep hæmorrhages into the muscles are also of frequent occurrence. Eustace Smith believes subperiosteal hæmorrhage to be the most characteristic lesion of the disease. Strümpell says that deep extravasations are the peculiarity of scurvy, and that next in importance is the peculiar condition of the gums and mucous membrane of the mouth.

That infantile scurvy is not simply a rare curiosity among diseases is proved by the fact that at a meeting of the Academy of Medicine on February 15th a hundred and six cases were reported. Eight cases have since been added to the list, making a total of a hundred and fourteen authentic cases. Dr. Louis Starr, of Philadelphia, in a communication read at this meeting, reported thirteen

A vertical section of the thigh and leg in a case of infantile scorbatus (Case 2 in the table). The dark areas along the femur and tibia represent subperiosetal hemorrhage. (Drawn from a specimen preserved in the museum of the College of Physicians and Surgeons.)

cases, all in private practice and in the best of surroundings. All the patients recovered except one. The autopsy findings in that case were identical with those reported in this article. Dr. Forchheimer, of Cincinnati, in a communication read at the same meeting, reported ten cases. He believed that the diagnosis rested upon the hæmorrhagic nature of the symptoms, and that all conditions classed under the head of purpura, peliosis, etc., were in fact scorbutic in nature.

<sup>\*</sup> Based on a paper read by Dr. Northrup before the New York Academy of Medicine, February 15, 1894, and on clinical material collected and edited by Dr. Crandall.

He referred to the peculiar muddy complexion which was common in these cases, and laid especial stress upon the result of treatment as an important point in the diagnosis. Dr. Rotch, of Boston, had seen nearly forty cases. He was in serious doubt whether such a disease as acute rhachitis existed. Some of his cases had been superadded to rhachitis. After recovery of the scurvy, the rhachitis took the usual slow course. Dr. Blackader, of Montreal, and Dr. Booker, of Baltimore, had not met with scurvy in infants.

There is without doubt some uncertainty regarding both the true nature of scurvy and its true causes. There are probably certain obscure hemorrhagic conditions which are scorbutic in character. The ordinary cases, however, present a remarkably uniform collection of symptoms. A case which occurred in the practice of one of the writers presented the following very typical history of scurvy in an early stage:

A male child of thirteen months had been nursed for three months. It was then weaned and fed on cow's milk for four months, then on Nestle's food, then on Mellin's food with a small proportion of milk, and finally for six weeks, at the advice of a friend, almost exclusively on prepared barley. For several weeks the baby had been fretful and cross and for two weeks had been especially irritable and had evinced pain when handled. It was inclined to lie quiet and was irritable when disturbed.

Blood had been noticed twice on the lips, but had been attributed to injury from a rough nipple. Swelling above the right knee had been noticed for twenty-four hours and it was remembered that the child had not moved the leg naturally for several days.

On examination, the child was found to be anemic and showed moderate signs of rickets. There were four teeth. The gums around each tooth were dark red and spongy, and, on pressure, bled slightly. The slightest movement caused the child to cry out with pain, and this was most marked when the hips or legs were moved or pressed upon. The right thigh was considerably swollen, the skin being tense and slightly red. It was excessively sensitive to pressure, but did not pit. There was also slight tenderness at the hip. The child was drawn up in a peculiar attitude with the legs flexed. On the leg there were one or two spots slightly discolored, but there was no distinct purpura. The treatment consisted solely of top milk, beef juice, and orange juice. Improvement in the gums was noticed in two days. The soreness rapidly decreased, and there was complete recovery from all other symptoms in less than three weeks.

Of the hundred and fourteen cases referred to, a detailed history has been obtained in thirty-six. These histories are presented in the accompanying table. It has been impossible to enter all the details in many of the histories. Certain facts are referred to, therefore, which do not appear in the table.

-										
No.	Age.	Sex.	Attendant.	Surround- ings.	Symptoms.	Lesions, signs.	Diet.	Treatment.	Course.	Remarks.
1	16 mos.	F.	W. P. Northrup, New York,	Private.	Pain on motion; no rickets; anæmia.	Swollen right thigh; spongy gums; no ecchymoses.	Proprietary food almost exclu- sively.	Correct diet (milk, beef juice), orange juice.	Improved in five days, markedly in ten days, well in thirty days.	Had been mis- taken for rheu- matism.
2	18 mos.	F.	W. P. Northrup, New York.	Foundling asylum.	Pain; anæmia; metallic pallor; temperature, 101°; passages black.	Swelling, both thighs and knee; gums bleeding; "black eve."	Nursed by woman also nursing her own child.	Vegetable acids.	Died of pneu- monia; autopsy.	
3	6 yrs.	М.	R. Van Santvoord, New York.	Idiot asylum.	Not reported. Pa- tient a helpless idiot; confined to bed.	Extensive hemor- rhages at upper end of both humeri.			Died; autopsy.	Diagnosis made only after death.
4			A. Caillé, New York.	Private.		Subperiosteal effu- sion of blood; swelling: ecchy- moses, skin and gums.	••••••		Died; autopsy.	
5	12 mos.	F.	C. H. Richardson, New York.	Dispensary.	blood passed from bowels and stom- ach; temperature,	Subperiosteal effusion, both legs; spinal curvature; gums soft.	Improper diet ; condensed milk.	"Live diet," orange and lemon juice.	Purpuric spots disappeared in three days; case lost sight of.	Blood effusion proved by hy po- dermic needle.
6	2 yrs.	М.	H. Goldenberg, New York.	Dispensary.	No rickets; bleeding from nose, mouth, bowels;	Feet, legs, scrotum swollen; gums spongy, bleeding; profuse ecclymoses.	Milk diet ex- clusively.	Fresh vege- tables, lemon juice, chlorate of potassium.	Child well in a few days.	Gangrenous spots in pharynx; breath fætid.
7	16 mos.	М.	W. P. Northrup, New York.	Private.		Hemorrhages about one ankle; spongy	Proprietary food exclusively.	Lime, hydro- chloric acid, tincture of iron.	Slowly and grad- ually recovered.	Had been diag- nosticated as rickets.

	-	1						'		

Sex is referred to in thirty-two cases—sixteen being males, sixteen females. The youngest patient was four | shows that twenty-six patients were seen in private practice months old, the oldest was an idiot of six years. Twenty- and ten in institutions or dispensaries. In fourteen the eight children (seventy-nine per cent.) were between eight surroundings were stated as being excellent, rich, or luxurimonths and eighteen months; twenty-two children (sixty-ous. In but two cases were the surroundings of private three per cent.) were between nine months and thirteen patients stated as especially bad. The surroundings of inmonths. The disease is most common, therefore, at about stitution patients were especially poor in five instances, the end of the first year of life.

Investigation of the surroundings and social condition Ten of these children lived in the country or in small towns. It is evident that scurvy is not essentially a disease of large cities, and especially not of tenement-house regions. Unhygienic surroundings in themselves are clearly not an important feature in its production. Some of the worst cases reported occurred in families in which the children received the most painstaking care. Other causes must therefore be sought.

The most evident and probably the most active cause of scurvy is improper diet. The exact diet is known in thirty-three cases. We find that twelve of these children (thirty-six per cent.) were fed on a proprietary food exclusively; six (eighteen per cent.) had received an exclusive diet of condensed milk or evaporated cream, while three received a combination of these two foods. Over sixtythree per cent., therefore, were fed upon a diet of proprietary foods and condensed milk. Two children received sterilized milk exclusively and three a weak mixture of milk and water. One was fed on condensed milk, one on boiled and peptonized milk, one on barley water. Two were asylum babies who were "boarded out." In only one was fresh milk the exclusive diet, but it was not stated whether it was given pure or diluted. It is seen, therefore, that improper methods of feeding were pursued in every case with perhaps a single exception. The experience of most observers agrees with the facts here presented, that the exclusive use of a proprietary food or of evaporated milk is the most common accompaniment of scurvy. No one food seems to be a special offender, except as it is more generally used. The one food which is probably the most largely used in this country was mentioned most frequently. Should it come into general use it would no doubt obtain the monopoly on scurvy, though it would probably not exhibit its scurvy cases in its public advertisements.

Sterilized milk also is believed by some to be capable of producing scurvy. The evidence seems to be undoubted that milk sterilized for a long time at a high temperature has caused this disease. The statement made by Holt, that in three great institutions of New York city where infants are fed almost exclusively on sterilized milk not a single case of scurvy has developed in five years, would seem to show that where this process is not carried to an unreasonable degree no danger is to be apprehended. No such charge has been made against Pasteurized milk, which is a safer food for a variety of reasons. Sterilized milk requires as careful modification as raw milk. If it is not properly modified it may cause serious disturbance. It is possible, as suggested by Winters, that lack of proper preparation has been a factor in certain cases as well as the sterilization. Sterilized milk has proved too valuable a food in large cities to be thoughtlessly set aside until it is positively proved to be unsafe. Weak milk mixtures seem to have been a causative factor in three cases. One of these, a child of eleven months, was fed upon nothing but milk diluted with an equal amount of water. Winters has recently drawn special attention to the fact that an excessively weak mixture may be an active cause of the disease.

Anæmia was definitely noted as present in fifteen cases, and as not present in but one case. Metallic pallor or ex-

treme sallowness was observed four times. The nutrition was noted as good in four cases. Malnutrition was specially noted seven times, and marasmus seven times.

Rhachitis was referred to nineteen times. It was to a marked degree present in five cases, and slight rhachitis in six. It was definitely not present in eight cases. In several instances the scurvy was referred to as being ingrafted upon or added to the rickets. When the symptoms of scurvy disappeared under treatment, the rhachitic condition remained unchanged and disappeared slowly. Those who have seen most scurvy seem to be most skeptical as to the existence of such a disease as acute rhachitis. In some cases it is certain that the condition described under that name is, in fact, scurvy superadded to rickets.

The condition of the bowels was referred to in nine cases. Diarrhœa was present in six; constipation in two. In one case they were regular. Diarrhœa has been especially noticed by Carr.

Fever was frequently noted, and was commonly intermittent in character. It rarely went above 101°, but occasionally reached 103°. It seemed in many instances to be an integral part of the disease, but sometimes it seemed clearly due to other causes.

Pseudo-paralysis is an interesting and very important symptom, which may readily mislead the unwary. In a paper read before the Academy of Medicine, Dr. Henry Ling Taylor reported two marked cases. He believed that essential paralysis could not be attributed to scurvy, but that the condition was due to the pain caused by contraction of the muscles on their tender periosteal attachments. This might become so intense that all motion would be instinctively avoided. When joint irritation existed, there would be local reflex muscular rigidity, which would also operate to prevent motion. It was to be distinguished from other paralytic affections by the accompanying symptoms of scurvy, normal knee reflexes, and speedy subsidence on antiscorbutic diet. The spine and upper extremities were sometimes affected, but more commonly the lower extremities were alone involved. Pseudo-paralysis was definitely present in nine cases. It involved one leg in one case, both legs in three, legs and arms in one. Two children were reported as perfectly helpless, and in two cases the location was not stated. In no instance did the paralysis persist after the subsidence of the scorbutic symptoms. The diagnosis of infantile paralysis had been made in no fewer than three of these cases, and one had been treated for some time by electricity.

Pain was more common than any other symptom. It was, in fact, present in every patient in whom its presence or absence was noted. It was specified as in the legs in ten cases and in the arms in three. It was usually severe and often so excessive as to cause the child to scream out with fear at the approach of the attendants. It was commonly marked only upon motion or handling. The child suffering from scurvy is therefore inclined to lie quietly in any position in which it is most comfortable. As a rule, the legs are slightly flexed.

Passages of blood were noted from the stomach in two cases, from the bowels in four, from the nose in two, and from the bladder in two; it was definitely noted as not present in but three patients. In the remaining cases no mention was made of this symptom.

Subcutaneous hæmorrhages were noted in at least fifteen cases; "purpura" was observed seven times; "petechiæ," three times; "ecchymoses," five times. In one child a vaccination scar two months old became ecchymotic. In three cases hæmorrhage took place in the eyelids, causing "black eye," and adding greatly to the wretched appearance of the little sufferer.

The condition of the gums was noted in thirty-two cases. In two instances there were no teeth, and the gums were neither spongy nor bleeding. This peculiarity has been recorded by numerous observers. When a few teeth only have appeared, the changes in the gums are, as a rule, limited to the gums bordering these teeth. In twenty-four cases the gums were described as spongy, inflamed, or purple. In three cases they were described as ulcerated, and in three as simply bleeding. Actual bleeding of the gums was noted in nineteen cases. The condition of the gums was therefore one of the most constant and characteristic symptoms.

Swelling of the extremities was noted in thirty-three cases. The skin over the swelling was, as a rule, tense and shining; it was often purplish or livid, but sometimes appeared normal in color; it was of normal temperature, and did not pit on pressure. As the swelling subsided, thickening of the shaft of the bone was in some instances detected. Liability to fracture at the epiphyses was a marked feature.

In ten cases both legs were said to be involved, and in one one leg, but the exact location of the swelling was not mentioned. In the remaining twenty-two cases in which the exact location was noted the thigh was involved sixteen times, the leg below the knee thirteen times, the ankle five times, the knee four times, and the arm three times. The accompanying table shows the various locations of the lesions:

One thigh	4
Both thighs	4
Both thighs and legs	3
Both thighs, legs, and forearms	2
One thigh and one knee	1
One thigh and one ankle	1
One thigh and one leg	1
Both legs, feet, and scrotum	1
One leg and one humerus	1
Both knees and ankles	3
One ankle	1
	_

The results of antiscorbutic treatment are, almost without exception, very brilliant. Many of these children were treated at first by general tonics, acids, phosphorus, or chlorate of potassium. The result of such treatment, without exception, was unsatisfactory. It seemed in most instances to produce no effect whatever upon the course of the disease. The subsequent improvement under antiscorbutic regimen was therefore especially gratifying to the attending

physician. The one thing absolutely necessary to insure a cure is fresh food. Fresh cow's milk is, by all means, the most important element. It is both food and medicine. It should be properly diluted and prepared to meet the requirements of the case. It is well to combine it with a cereal, as Jacobi has suggested. If it requires diluting, barley water may be employed. In warm weather it may be Pasteurized, or even moderately sterilized. Expressed beef juice is a valuable adjuvant in many cases. There seems but little doubt also that orange juice is an element of decided value. Children will certainly recover without it if put upon a proper diet, but the evidence seems decided that it aids materially in the cure of these cases. It has the merit of being easily administered, for these little sufferers, without exception, take it with marked avidity. When rhachitis is present it is best to administer phosphorus, which may be given in the form of the official elixir. The condition of the stomach and bowels should also receive attention, and tonics are not contraindicated. It should be clearly understood, however, that all drugs are unavailing for the cure of scurvy, and are secondary to milk, beef juice, and orange juice. The swollen and painful extremities may be sometimes relieved by inunctions with oil. The child should be handled with the greatest care, not only to avoid unnecessary suffering, but because there is especial liability to fracture of the bones.

It seems probable that scurvy is increasing in frequency. The more general use of patent and evaporated foods to the exclusion of milk will certainly have the result of increasing the number of these cases. It is quite certain, however, that the disease is not a new one, but has been overlooked or mistaken for some other condition. Excluding the diagnosis of acute rhachitis, rheumatism seems to have been the mistaken diagnosis in the greater number of cases. Several cases have been treated simply as purpura, two or three as ulcerative stomatitis, three as infantile paralysis, and one or two as simple rhachitis. One case within the writer's knowledge was considered to be a sarcoma of the knee; two cases had been treated as osteitis of the knee.

In the light of our present knowledge we may draw the following conclusions:

- Scurvy may appear at any period of infancy or early childhood, but is most common between the ninth and fourteenth months.
- 2. The lesions are hæmorrhagic in character, due probably to diapedesis. The most characteristic are subperiosteal hæmorrhages. Hæmorrhages into the muscular tissues, into the skin, and mucous membranes are more or less constant.
- 3. It occurs in every grade of the social scale, but is more frequent among the rich than among the poor. The neglected child who eats everything at the table may become rhachitic or marasmic, but he obtains enough fresh food to protect him from scurvy. It very rarely occurs in asylums and hospitals, because in recent years feeding in such institutions has been more rational than in many private families.
  - 4. Lack of fresh food is the most important cause

The use of the proprietary foods and condensed milk produces more scurvy than all other causes combined. Even fresh milk in small proportions is not sufficient to insure protection.

- 5. Anæmia and malnutrition are almost invariably present; a peculiar sallow complexion is common.
- 6. Scurvy is frequently superadded to rhachitis, but in a considerable number of cases no evidences of rhachitis are present. So-called acute rickets is in most cases, probably in all, rickets complicated by scurvy.
- 7. Pain is a constant symptom; it develops early and is usually intense.
- 8. A varying degree of immobility of the extremities is common, and is frequently so marked as to simulate paralysis. This pseudo-paralysis disappears with the subsidence of the scorbutic symptoms.
- 9. Subcutaneous hæmorrhages, as well as hæmorrhages from the cavities of the body, are very common, but are not necessary to a diagnosis of scurvy.
- 10. The condition of the gums is characteristic. They are purplish, soft, spongy, and bleeding, and frequently show decided ulcerations. When the teeth have not been erupted, changes in the gums are usually slight or entirely absent.
- 11. Painful swelling of the lower extremities is the most constant symptom; the upper extremities are rarely involved. The thigh is affected more frequently than any other region.
- 12. Children suffering from scurvy commonly present the following symptoms: Anæmia, intense pain on motion, spongy and bleeding gums, swelling of the lower extremities, usually at the thigh. There may also be purpura or ecchymoses, discharge of blood from the various cavities of the body, and pseudo-paralysis.
- 13. Scurvy, when untreated, is a very fatal disease; when recognized and properly treated, a rapid and complete cure is usually effected. The result of antiscorbutic treatment is, in fact, one of the most certain means of diagnosis.
- 14. Scurvy may be mistaken for rheumatism, stomatitis, rickets, sarcoma, osteitis, and infantile paralysis.
- 15. Scurvy is a dietetic disease and must be cured by dietetic treatment. Fresh milk, beef juice, and orange juice are the most effective remedies.

#### THE THERAPEUTIC USES OF SPARTEINE.\*

By DAVID CERNA, M. D., Ph. D.,

GALVESTON.

GALVES

In a paper which I had the honor of reading before the Texas Academy of Science last December, I fully discussed the physiological actions of sparteine. From a study of the literature of the subject, and particularly from the results obtained in my experimental research, I have found, in corroboration of previous experimenters, that sparteine, one of the active principles of Cytisus scoparius

\* Read before the Texas State Medical Association, at Austin, April .24, 1894,

or Sarothamnus (?) scoparius, or common broom-plant, is, not unlike digitalis, a decided stimulant to the general circulation. On the dog, I found that the drug, given hypodermically or intravenously in what may be called therapeutic amounts, acted particularly as a cardiac stimulant, increasing the arterial pressure and the force of the pulse. The rate of the heart-beat is at first somewhat accelerated, and is soon followed, however, by a distinct slowness, but the energy of the cardiac contractions is considerably increased, as evidenced by the large size and fullness of the individual pulse waves. This augmented cardiac force is also observed when the drug is applied directly to the batrachian viscus in situ, or when the isolated heart of the frog is placed in a sparteine solution, as well as when it is administered subcutaneously to other animals or to man. Large doses cause a fall of the arterial pressure, and even when the column of mercury in the manometer is far below the original height the increased cardiac energy is apt to persist. I have likewise noticed that under poisonous amounts of the agent the heart usually ceases in systole, and generally after the stoppage of the respiration, death being therefore produced by failure of the latter function. The drug undoubtedly acts powerfully upon the heart itself, whether on its intrinsic ganglia, or on the cardiac muscle, or on both; it exercises some action on the vaso-motor system also. For a fuller consideration of the physiological actions of sparteine on the circulation and on other portions of the animal economy I refer the reader to my previous paper.\*

As a therapeutic agent sparteine is but sparingly spoken of in the text-books. Such a disregard for a useful remedy, it seems to me, is not justifiable. In carefully looking over the literature pertaining to the use of this agent in practical medicine (the largest number of references at my command were kindly furnished me by my former learned teacher, Professor Alfred Stillé, of Philadelphia, to whom I herein wish to express my obligation), I find that it has been tried by a considerable number of clinicians, and generally, as will be seen, with good results. I believe it will be proper for me to give a brief summary of these studies before giving my own experience and that of other gentlemen who have been kind enough to assist me in the matter.

Sée † affirms that the drug is valuable in cardiac affections, increasing diuresis; that it is superior to other heart remedies in its ability to control general nervous excitement and in its power to regulate an irregular pulse. In a later observation the same writer comes to regard the medicament as an auxiliary to other cardiac remedies. The views of Sée in regard to the properties of sparteine as a heart tonic have been confirmed in the main by Buckler, # Roland, | and Voight. Foy () found it as a heart tonic a good substitute for digitalis and convallaria.

Medical Press and Circular, xli, 121, 1886.

Leo\* finds that sparteine causes no increase in the amount of urine in healthy individuals. He recommends it in cardiac disease, especially when there is lack of compensation and it is then desired to produce diuresis. On the other hand, Prior† believes that even in health, under certain circumstances, the agent is capable of exercising a diuretic action. He regards it as more useful in valvular lesions than in disease of the cardiac muscle. The same writer tried it in bronchial asthma, but without any good results.

Gluzinski; observed that the medicament slowed the heart's action and increased the arterial pressure. In his opinion, sparteine, though less powerful than digitalis, is more rapid in its action, and therefore may be used when there is danger in delay. He does not believe that sparteine removes cardiac arrhythmia. A similar opinion has been expressed by Stoessel, who considers sparteine inferior to digitalis in cardiac arrhythmia. In his experience, again, the drug exercises no influence in fatty degeneration of the heart, and he further found it without power as a diuretic.

Langgard | has reported eighteen cases of heart disease in which sparteine produced beneficial results, results which have been more or less corroborated by Clarke. A This latter observer has arrived at the conclusion that sparteine can be used with advantage in heart disease, particularly hypertrophy, when digitalis is contraindicated. He found in general that the remedy slowed the rate but increased the force of the pulse, causing at the same time a rise of the arterial pressure. The forms of disease treated with sparteine, with the effects produced, are thus specified by Clarke: 1. In mitral regurgitation the results were very striking. 2. In mitral stenosis the benefits were less and less pronounced. 3. In aortic regurgitation, with greatly enlarged and excited heart, small doses were useful. 4. In asthma the influence was good, but very tardy. 5. In palpitation, without organic disease of the heart, the relief was immediate; and, 6. In Graves's disease it occasioned great improvement.

Pawinski \( \) studied the drug very carefully in thirty-three cases, and found that it produced diuresis, no disturbances of digestion, and that it had no cumulative action; that the effects of the remedy became pronounced in from thirty to forty minutes after its ingestion. He also found it serviceable in the functional cardiac disease of neurasthenic and anæmic individuals, and of heavy drinkers and excessive smokers. Similar good results were obtained in asthma, Graves's disease, chronic bronchitis, and emphysema, particularly in those cases in which digitalis was not tolerated. The author, however, warns against the use of the medicament in cases in which the cardiac muscle is believed to have undergone degeneration.

Maslowski\* employed the remedy in three cases of cardiac disease, and found it a rapidly acting and powerful heart tonic and diuretic. In his experience the drug had no cumulative action. Identical observations have been made by Livierato † and Fereira.‡ The latter author obtained excellent results in functional and organic affections of the heart, and further believes sparteine to be of special service in those cases in which digitalis is contraindicated.

Pawlow # thinks that sparteine is only indicated in cases in which compensation is undisturbed, while, on the other hand, Kurloff || believes the remedy only useful in cases where there is lack of compensation without organic lesion—that is, in those cases in which more energetic drugs are contraindicated.

Levaschew a is of the opinion that sparteine is capable of promptly re-enforcing and controlling a weak and irritable heart. In his hands the remedy has proved successful in steadying the pulse and the respiration. He, however, has found it powerless in degeneration of the cardiac muscle, and again in those cases in which the ædema was excessive. He further observed that in cases of cardiac disease the remedy causes an increase in the amount of urine secreted. Though not asserting the fact, the author has thought that sparteine produced digestive disturbances, and, on the whole, considers the drug inferior to digitalis, adonis, and strophanthus.

L. A. Gluzinski ◊ found sparteine useful in the first stages of heart failure, and states, further, that the medicament is prompt in its action.

Tyson reports an obstinate case of dropsy in which sparteine gave excellent results as a diurctic. \*\*\* Solis-Cohen ||| states that the remedy is useful as a cardiant diurctic, and even superior to digitalis, especially when combined with caffeine.

Quite recently Bacon \* records a striking case of valvular disease of the heart, following inflammatory rheumatism, in which sparteine acted promptly and effectively. The author affirms to have used the same agent in two cases of mitral disease, with failing compensation and dropsy, with excellent results, and believes it to be one of the most reliable drugs at our command for the relief of such conditions. He has observed that under the action of the medicament the heart's action becomes more regular, and that the daily amount of urine is increased. The same writer reports a second case t of acute endocarditis complicating inflammatory rheumatism, which steadily grew worse under routine treatment. When the heart was intermittent every third beat, with great irregularity, and the radial pulse was hardly perceptible, sparteine was administered in doses of a quarter of a grain every four hours. The effects were noticed in thirty minutes after the first dose, and in two hours the increase of the cardiac force was marked. After the third dose the labored dyspnæa began to lessen and the heart was gaining force; after six hours the pulse ceased to intermit, and in twenty-four hours was nearly regular and quite strong. No ill effects were observed, the patient being a girl eleven years of age.

Though not in a very extended manner, I myself have tried sparteine in practical medicine. Here I have found the drug to act not only as an energetic heart tonic, but also as an excellent diuretic. In the former instance—that is, as a cardiac stimulant—I have employed the remedy, with most satisfactory results, in nervous palpitation, in irritable heart due to excessive use of tobacco, and in that similar condition of the viscus caused by mere muscular weakness or loss of inhibitory power.

I have observed good effects following the use of the drug not only in functional disorders of the heart, but likewise in valvular affections. In these cases, and much more particularly in those in which digitalis is contraindicated or not well borne, sparteine is highly beneficial, and not perhaps as a curative agent in most instances, but simply as a regulator of the circulation, thereby causing, at least for the time being, a more or less prolonged relief. Again, in dropsies of cardiac origin as well as in those depending on renal disease, the drug under consideration has produced as a diuretic marked results in my hands. The action of sparteine on the circulation is very decided, and it is probably due to a local increase of the arterial pressure in the organ, the result of a general action, that the drug enhances the activity of the kidney, for, so far as has been determined by experimental studies, sparteine possesses no true diuretic virtues like caffeine, for instance, which directly stimulates the renal epithelium.

In breathlessness occurring in obese persons, due probably to a fatty infiltration of the heart, as well as in the shortness of breath of anæmic patients, the employment of sparteine has been followed by decided benefit, and similar results have I observed in cases of bronchitis and in a considerable number of asthmatic individuals.

It may be said, indeed, that the range of usefulness of sparteine is not a limited one, yet the chief service rendered by the drug in the treatment of disease, not only as a substitute for more powerful medicaments belonging to the same class (like digitalis, strophanthus, adonis, convallaria, etc.), but as a prompt cardiac and renal stimulant in itself, is made manifest particularly in those conditions characterized by a weakened circulation due either to functional or to organic changes. The remedy generally relieves and sometimes cures. I have never seen disagreeable, much less poisonous, effects following the administration of the drug even when ingested in comparatively large quantities, and I may here suggest that the failure of this agent to do good in the hands of some practitioners has been, I believe, chiefly due to the fact that it has not been employed in proper doses or for a sufficient length of time. Probably, on the other hand, the quality of the drug used has been overlooked. I have administered sparteine by the mouth or subcutaneously as the sulphate, and in this form it has generally produced the desired effects.

I am so convinced of the stimulating action of sparteine upon the circulation that I fully concur in the opinion of Sée\* in that this drug, as far as our knowledge goes, is superior to all other similar remedies in its ability to steady the most irregular pulse. Hence, as noticed by various observers, chiefly Pawinski,† Clarke,† Wood,\* and others, the usefulness of sparteine in such diseases as exophthalmic goitre, in which an irregularity of the cardiac action is a prominent and often most distressing symptom. I myself have treated cases of this latter affection with most striking results, using sparteine to the exclusion of all other heart tonics.

Indeed, next to digitalis, sparteine has been, according to my experience, the most effective stimulant to the circulation, and often has given me more satisfactory results than the former remedy. Sparteine, though less powerful perhaps than digitalis, the prince of cardiac stimulants, has a very decided advantage over the latter agent in that it has no cumulative action. But to illustrate my individual experience in the therapeutic applications of sparteine, I may venture to describe, as briefly as possible, the following cases, and in so doing I will endeavor to avoid unnecessary details:

Case I. Valcular Lesions traceable to Acute Articular Rheumatism.—F. G., aged thirty-two years, married, no children. Family history apparently good; no syphilis. Patient suffered from infantile disorders such as measles, whooping-cough, etc. At about twenty years of age had a mild attack of typhoid fever, but made a speedy recovery. About six years previous to present illness suffered from articular rheumatism brought on by exposure to cold and dampness. When first seen by me patient had been sick for about three months. Complained of pain in joints and over præcordial region; was dyspneic; had a temperature of 101° F. (38-3° C.), with slight remissions; pulse, 128 a minute, weak and irregular; respiration, 38; expression anxious. Physical examination revealed, on percussion, an enlarged area of dullness over the cardiac region, and

<sup>\*</sup> The rapenties; its Principles and Practice. Eighth edition, 1891

on auscultation, a harsh murmur, apparently diastolic, extending over to carotids; signs of both mitral and aortic regurgitation. Albumin in urine; daily quantity of this fluid about thirty ounces (850 grammes). Insomnia. Patient was placed on a strictly milk diet, etc. lodide of potassium, quinine, alternating with some of the coal-tar derivatives, carefully watched, were given. No improvement in the course of a month. Patient was then put on the sulphate of sparteine exclusively, in doses of a quarter of a grain (0.015 gramme) three times a day. No marked changes occurred in a week. I then increased the dose to half a grain (0.03 gramme) three times a day and resumed the potassium salt. Improvement soon followed. By the end of another week the pulse was steady and strong-98 a minute; respiration, 22; the flow of urine was increased, the fluid measuring from sixty to eighty ounces (1,700 to 2,265 grammes) a day, with a notable diminution in the amount of albumin; bodily temperature, 99° F. (37.2° C.). Patient slept better. The same treatment was continued, and in about a month longer the bodily temperature had regained its normal standard; pain in the joints was almost gone; pulse, 85; respiration, 20; urine free from albumin, and nearly a hundred and seventy ounces (4,815 grammes) in amount in the twenty-four hours; præcordial distress absent. Discharged patient, and in two months he reported himself as still in a comfortable condition, with good appetite, and able to take light exercise in the open air.

Case II. Cardiac Dilatation with Lack of Compensation .-G. V. G., aged fifty-two years, farmer, with good family history. Patient had for some years complained of shortness of breath after slight exertion. Had been advised to stop all physical work. The man was suffering from a chronic mitral lesion. During an attack of influenza his old heart trouble had been much aggravated, but under proper treatment and good nursing he had entered into convalescence from the grippal disease. One afternoon, shortly after partaking of a good meal, the patient became suddenly faint, with a sense of distress over the præcordia, dyspnæa, and a feeling of approaching dissolution. In the course of a few days bronchitis supervened, followed soon afterward by general ædema. When first seen this symptomatology was noticed: Marked cyanosis of the skin; general ædema, pulsation of jugular veins; regurgitant murmurs in mitral and tricuspid regions; intense dyspnœa; pulse feeble, irregular, and rapid, about 140 a minute; respiration, 42; urine scanty and albuminous; insomnia. Diagnosis being apparently clear, patient was given digitalis; but this remedy seemed to aggravate the condition, and was therefore immediately substituted with sparteine in doses of half a grain (0.03 gramme) every three hours. After the fourth dose the patient felt intense relief, his breathing became regular and easy, only 28 a minute; pulse steady, full, and strong, 92 a minute; there was a good flow of urine. The remedy was kept up in doses of half a grain (0.03 gramme) every three hours, and in the course of three weeks, with a gradual improvement of the respiration and the circulation and the renal function, the ædema, the cyanosis, and even the bronchial trouble had practically disappeared. The sparteine was gradually diminished in amount, and the patient continued to do well for a couple of months longer. One day, while attempting to walk upstairs in a hurry, he fell over and in a few minutes died. No autopsy was allowed.

Case III. Chorea associated with Endocarditis.—Y. L. M., aged ten years. Patient rheumatic; family history uncertain, but probably also rheumatic. The boy had had scarlatina and measles when quite young, and had suffered from chorea for the last six years. While apparently in good health (except his choreic trouble, for which he had never been treated), after exposure to cold and dampness, he developed a bodily temperature of 105.8° F. (41° C.), accompanied with intense headache and

marked dyspnœic symptoms; coated tongue, thirst excessive, and profuse perspiration. Examination showed almost entire absence of cardiac impulse; præcordial pain; weak, irregular, and compressible pulse, 138 a minute; respiration, 42; cyanotic condition of surface of the body; constipation; scanty secretion of urine. On Monday, after moving his bowels with a gentle laxative, patient was put on quinine and salicylates. Wednesday, no apparent improvement as yet; temperature, 102.2° F. (39° C.); respiration, 40 a minute; pulse, 142 a minute and growing weaker and more irregular, sometimes distinctly intermittent; secretion of urine about the same as before. Suspended the quinine, but continued the salicylates. Saturday, a slight improvement was noticed, but the pulse was exceedingly weak and alarmingly rapid, 150 a minute; respiration, 44; temperature, 100.6° F. (38.1° C.); dyspnæa distressing. The salicylates were now discontinued also and the patient was put on sparteine sulphate, a quarter of a grain (0.015 gramme) every three hours. After the third dose the dyspnœa became better. On the next day I found decided improvement; patient had passed a good night, and was now breathing a great deal easier; respiration, 32; pulse stronger and more regular, 104 a minute. An increased flow of urine was noticed by attendants, but the quantity was not ascertained. Continued the administration of sparteine in doses of a quarter of a grain (0.015 gramme) three times a day. There was a gradual but decided amelioration, and four days afterward the bodily temperature was about normal; appetite very good; sleep at night also very good; pulse quite strong now, full, and regular, 98 a minute; respiration, 28 a minute; kidneys very active. In a week longer the patient got out of bed. Suspended the sparteine and put him on a tonic. Several days later the pulse became faster and somewhat irregular, and the patient was given sparteine once more for another week, with the same good results. The effects on the general circulation, particularly the heart, and on the kidneys were distinctly beneficial.

CASE IV. Exophthalmic Goître.-Miss J. del C., aged seventeen years, of a lymphatic temperament; anæmic. Family history good. Menstruated at fifteen, but periods irregular and scanty. Had been suffering from present disease for several months and had been treated unsuccessfully by able physicians with various medicaments and even with electricity. Now she was also troubled with distressing palpitations, dyspnœa, and fainting spells; blushed and perspired under the slightest provocation; digestion bad; bowels, though not constipated, very irregular; insomnia; great nervous depression, with suicidal tendencies. Patient weighed ninety-two pounds. Physical examination showed systolic murmur over the apex; heart sounds feeble. The typical signs of exophthalmic goître were marked, especially the rapidity of the heart's action, the organ beating from 158 to 170 a minute; prominence of eyeballs and enlarged thyreoid glands, with distinct throbbings of both carotids; respiration, 38 a minute. I learned that she had taken alternately digitalis, strophanthus, and belladonna, but, as mentioned, with negative results. Without further ado, the patient was put to bed and subjected to a strictly liquid diet, especially of milk. Sparteine sulphate, in doses of half a grain (0.03 gramme) every four hours, was administered at first. After two days the patient felt somewhat but not much better; pulse still weak and irregular, about 162; respiration, 34. She was now passing from twenty-eight to thirty ounces (718 to 855 grammes) in the course of the day. Increased the sparteine to half a grain (0.03 gramme) every three hours on Tuesday morning. On Thursday I found decided changes; breathing more easy, 26 respirations a minute; pulse fuller and stronger, 128 a minute; urine had increased to thirty-eight ounces (1,080 grammes) a day. Friday-pulse, 102; respiration, 24; no dyspnoa; amount of urine in the course of the day, forty-eight ounces (1,370 grammes); appetite much better and sleep more refreshing; patient more cheerful, with a desire to get out of bed. A week later, the change in the patient's condition was remarkable. Both respiration and pulse apparently normal; the former, 22; the latter strong, fuller still, and only 88 a minute; amount of urine now varied from fifty to seventy ounces (1,925 to 1,995 grammes) a day, the fluid being practically normal; no albumin; acid reaction; specific gravity, 1.022. The thyreoid gland was distinctly lessened in size, and the prominence of the eyeballs had apparently disappeared. Appetite almost ravenous; condition of the bowels practically faultless. The patient had become extremely cheerful and, to use her own words, "felt all over like a new person." She was allowed now to get out of bed and instructed to do light bodily exercise. The drug was suspended for several days, during which time the patient did not feel very well; but she continued to improve on the readministration of the medicament, which was ordered in doses of a quarter of a grain (0.015 gramme) three times a day. In the course of about four months the ninetytwo-pound girl made the scale mark one hundred and twenty pounds. I lost track of the patient shortly afterward, but two years later I heard that she had been married and become a happy mother.

I do not think it is necessary for me to detail other cases of disease characterized by circulatory changes, and in which sparteine has, in my hands, rendered signal service. The cases I have given fairly represent the main results obtained by me with this valuable drug, destined, if not entirely to replace digitalis, at least to rival it in the treatment of heart affections, or in that of other maladies complicated with serious cardiac disturbances. As already stated, my own experience corroborates also that of other observers in regard to the diuretic properties of the drug under consideration. I could cite several cases of cardiac and renal dropsies in which sparteine, used from the start, gave excellent results as a diuretic, and still other cases that have been greatly benefited by this remedy, cases in which medicinal agents like digitalis, strophanthus, and others of the same class, tried first, had failed to do any good. But I desire to reproduce here, instead of any number of my own cases, two that have been kindly furnished me by Professor James Tyson, of Philadelphia, illustrating in a striking manner the diuretic properties of sparteine. In this connection I wish to thank my distinguished former teacher for his valuable assistance. Professor Tyson's cases are as follows:

Case V. Chronic Parenchymatous Nephritis.—Mrs. L., aged twenty-three years, was admitted to my wards in the Hospital of the University of Pennsylvania, August 23, 1893. She presented all the symptoms of chronic parenchymatous nephritis—dropsy, pallor, large albuminuria, numerous dark granular casts; also pale granular casts, and many compound granule cells. She was treated with caffeine citrate, digitalis, and sparteine at different times with varying results, all remedies being more or less efficient. With a view, however, to systematically testing the sparteine she was put on the drug after a suitable interval had clapsed, in doses of a quarter of a grain every two hours, on February 18, 1894. During the twenty-four hours previous the secretion of urine had been thirty ounces, and had ranged from a minimum of twenty-nine ounces to a maximum of thirty-eight ounces a day for eleven days preceding. On the 19th, the

twenty-four hours' secretion was forty ounces; on the 20th, sixty-four ounces; on the 21st, fifty-nine ounces; on the 22d, seventy-five ounces; on the 23d, sixty ounces. For three days there appear to have been no measurements, when, on the 26th, the twenty-four hours' secretion was fifty-four ounces; on the 27th, fifty-seven ounces; on the 28th, sixty ounces; on the 1st of March, seventy ounces; on the 2d, seventy-seven ounces; on the 3d, seventy-nine ounces; on the 4th, eighty-four ounces; on the 5th, eighty-six ounces; on the 6th, seventy-eight ounces; on the 7th, seventy-nine ounces; on the 8th, ninety-eight ounces; on the 9th, ninety-six ounces; on the 10th, eightyeight ounces; on the 11th, ninety-four ounces; on the 12th, ninety-three ounces; on the 13th, eighty ounces. On the 13th of March the sparteine was omitted, and on the 14th the urine had fallen to seventy ounces; on the 15th, to sixty ounces; on the 16th, to fifty-nine ounces; on the 17th the urine was again seventy-two ounces; on the 18th, seventy-nine ounces; and on the 19th it was once more only sixty-five ounces; on the 20th, sixty-two ounces; on the 21st, thirty-nine ounces. On the 22d the urine had arisen to sixty-nine ounces, but on the 23d it again fell to fifty-eight ounces. Thus it will be seen there was a direct relation between the administration of the sparteine and the secretion of urine, the latter increasing when the former was exhibited, and falling when it was discontinued.

CASE VI. Albuminuria. - Dr. W. R. B., aged thirty-four vears. Three years ago-that is, about January, 1891--albumin was discovered by a medical examiner for a life insurance company, having been previously unsuspected. No other symptoms appeared until about a year ago, when the patient began to have a little shortness of breath on exertion. In the summer of 1893 he went to Omaha to practice medicine, but found on arriving there that he could not sleep. He therefore returned to Philadelphia early in August and began to practice there. Soon after this, however, he had a convulsion, but recovered, and improved greatly for a time under the care of Dr. Robinson, of Camden, N. J. He again grew worse and sent for me on January 11, 1894. I found him gasping for breath, begging for something to make him sleep. His heart was exceedingly feeble, pulse scarcely perceptible at the wrist, but there was no murmur. On examining his urine I found a very large albuminuria, equaling three fourths of the bulk of the urine tested. There was also a large number of casts, hyaline and dark granular, with compound granules also free and adherent to casts. Sleep was obtained by chloral at first, but later morphine became necessary. He was put on the use of strychnine, with caffeine citrate at first, then digitalis, until the effect of these remedies ceased to be obtained. In the meantime the dropsy continued to increase until the skin of his legs burst, and there was constant weeping of serum, while there was also a large abdominal effusion. Sparteine sulphate was commenced on the 20th of February, when he was passing but a few ounces of urine and the dropsy was extreme. On the 23d four half-grain doses of sparteine were taken and the twenty-four hours' urine amounted to one hundred and three fluidounces. On the 24th, with three doses, the twenty-four hours' urine equaled seventy-nine ounces; on the 25th, with four doses, sixty-one ounces; on the 26th, with three doses, seventy-nine ounces; on the 27th, with three doses, fifty-eight ounces; on the 28th, with one dose, forty-three ounces; on March 1st, with four doses, forty-nine ounces; on the 2d, with four doses, eighty-nine ounces; on the 3d, with three doses, forty-six ounces; on the 4th, with four doses, eighty-three ounces; on the 5th, with two doses, fifty-four ounces. On March 6th no sparteine was given, and the twentyfour hours' urine fell to thirty-two ounces. On the 7th, with four doses, the amount of urine in the twenty-four hours was sixty-four ounces; on the 8th, with one dose, sixty-eight

ounces; on the 9th, with one dose, forty-eight ounces; on the 10th, with three doses, eighty-two ounces; on the 11th, with three doses, sixty-four ounces. On the 12th no sparteine was given, and the urine fell to thirty-eight ounces. On this day a small abscess in the leg was opened, which was recognized after the ædema had disappeared. By this time also the abdominal effusion had likewise disappeared. On the 13th no sparteine was administered, and the twenty-four hours' urine only measured twenty-six ounces; on the 14th, no sparteine, with the same result-that is, only twenty-six ounces of urine. On the 15th, the urine having fallen rapidly, sparteine was recommenced; two doses were given with only eighteen ounces in the twenty-four hours. On the 16th, with three doses, twentynine ounces; on the 17th, with three doses, twenty-six ounces; on the 18th, with six doses, twenty-seven ounces; on the 19th, with four doses, fourteen ounces. It was now concluded that sparteine had lost its effect, and digitalis was substituted in doses of fifteen minims every four hours. Simultaneously with the marked reduction in the amount of urine it was remarked that the shortness of breath returned in a troublesome way. At the end of the twenty-four hours after the digitalis was commenced the urine had attained fifty-one ounces. At the end of the next twenty-four hours, terminating at five o'clock on March 22d, with three doses of digitalis, the urine was sixty-eight ounces.

The results obtained in these two highly interesting cases speak for themselves. Dr. Tyson, whose authority in kidney disease is recognized the world over, is a firm believer in the diuretic properties of the drug. Referring to the two cases just described, he writes me as follows:

"I give you these cases without comment; but you will be able to see a markedly direct relation between the administration of the drug and the secretion of urine, notably increased with its exhibition and diminished with its withdrawal, although in Mrs. L.'s case, after the last withdrawal of the drug, the secretion fell to a less degree. I take it that when this happens the kidney is resuming its function. In the doctor's case, however, there followed not only a fall, but also a failure finally to respond, while the substitution of digitalis was promptly followed by an increase. It is, of course, necessary for the drug to have something to work on-that is, there must be fluid in the tissues or in some one of the serous cavities. In one instance I gave it to a young woman with astonishingly scanty secretion of urine, but no dropsy, but it was apparently without effect. Here, after a time, the freer ingestion of water was followed by a corresponding secretion. From the clinical aspect I am inclined to place it after digitalis, although I am not quite certain of this. You will note that I give larger doses than are recommended in the books-say, a quarter of a grain every two hours, or half a grain every four."

I need only add that I entirely agree with the views expressed by Dr. Tyson. There is scarcely any doubt but that sparteine, to exercise its diurctic action to better advantage; requires a suitable field. I myself, for experimental purposes, have taken the remedy with evidently negative results as regards an increase in the amount of urine secreted.

The same Dr. Tyson\* reported not very long ago a case of albuminuria occurring in a man forty-three years of age, in which the effects of sparteine as a diuretic were so striking that I will quote a portion of the details of the case. The author states:

"He was passing about forty ounces of urine. . . . I now (September 8th) added to this treatment sparteine, in doses of half a grain three times a day. It will be remembered that this drug had previously been given without effect, not, however, in connection with an exclusive milk diet, which was continued in the quantity of about forty-two ounces daily. It again appeared without effect, and on the 14th was substituted by the infusion of digitalis. The quantity of urine ranged from thirty-two ounces to forty-four until the 25th, when it rose to fifty-five ounces, and continued to rise with fluctuations until sixty-nine ounces were reached. Then there was some diminution, but the quantity continued free until about the 1st of November, when it began to decline until November 15th, when but twenty ounces were passed. Sparteine was again resorted to, and at once the urine rose rapidly and remarkably. Thus on the 16th there were twenty ounces; on the 17th, thirty-three; on the 18th, forty; on the 19th, fifty; on the 20th, seventy; on the 21st, one hundred and twenty-eight; on the 22d, one hundred and sixty-nine; on the 23d, one hundred and fifty-five; on the 24th, one hundred and fourteen; on the 25th, one hundred and forty-eight; on the 26th, one hundred and forty-nine. On the 26th the drug was discontinued, when at once there began a fall, the quantity being, however, still free."

Of the large number of prominent practitioners to whom I wrote requesting them to furnish me with their individual experience in the use of sparteine, the majority of them had little or nothing to say in regard to the matter, owing to their having employed the medicament to a limited extent or not at all. Those who have had some clinical experience with the drug kindly reported their observations to me, and I take pleasure in inserting their replies. I wish to thank all these gentlemen for their courtesy.

Dr. William Osler, of Baltimore: "I rarely now use sparteine. Some years ago I tried it in a series of cases of failure of compensation, and usually had to resort to digitalis. It has been in my hands very much inferior to either digitalis or strophanthus. I still occasionally order it when from any cause digitalis is not well borne and strophanthus fails."

Dr. Wharton Sinkler, of Philadelphia: "I have used sparteine in several cases of kidney disease where there was considerable suppression of urine, and was under the impression that its diuretic effect was decided. In one case which I recall I gave it hypodermically in doses of half a grain every four hours, and there was a marked increase in the amount of urine passed; but I did not observe any appreciable influence upon the pulse; in fact, there could be no fair test made of its action upon the heart, as I was giving strychnine at the same time."

Dr. J. M. Anders, of Philadelphia: "(a) In Acute Renal Affections.—In acute Bright's disease or acute nephritis with dropsy, it aggravates the local symptoms during the acute or febrile stage; but, after the acute stage is over, its use is followed by polyuria and rapid subsidence of the dropsical swelling. In these cases the commencing dose should be small (an eighth of a grain every four hours), gradually increasing to half a grain. In such instances I have found it to be a powerful diuretic. (b) In chronic nephritis (parenchymatous), with dropsy, its employment has not, in my hands, been followed by striking results. It is better to excite first vicarious climination through the skin and bowels; then sparteine sulphate, in combination with strychnine sulphate and digitalis, may be employed at intervals, with marked increase in the volume of urine, without unpleasant effects. It is, in my opinion, based on practical observation, a feeble cardiac stimulant and tonic. (c) Organic Disease of the Heart .-I have notes of some dozen cases of organic valvular disease in

which the remedy gave good results, though always most beneficial when combined with a powerful cardiac tonic, as digitalis. The cardiac dilatation is not improved by sparteine alone, whereas it is by digitalis; but the diuretic action of the latter drug is augmented by the use of the former in most cases. To overcome arrhythmia it is not as efficient as strophanthus and digitalis in combination, though it has some effect in this condition. In exophthalmic goitre I have had a limited experience with the drug, and, on the whole, favorable. How best to administer it in this latter disease I do not know precisely. It must, however, have an influence upon the vaso-motor nerves."

Dr. John V. Shoemaker, of Philadelphia: "I have found this remedy useful as a cardiac and renal stimulant. The cases in which I have employed it have been relieved or benefited according to the nature and stage of the disease. It possesses a decided advantage over digitalis in being free from a cumulative action. Although it has been denied that digitalis exerts such an influence, I am satisfied from my observations that, in certain instances, an effect due to accumulation does occur when digitalis has been administered steadily. After a patient has taken sparteine for several weeks it may be discontinued for several days, during which time it will be found that its characteristic effects are maintained. These properties render it extremely valuable for prolonged administration in chronic cases. I have given sulphate of sparteine with advantage in cases of enfeebled cardiac action from organic lesions, and also where the innervation of the organ was markedly disturbed. It is especially beneficial in disease of the mitral valve. In advanced stages of this condition, when dilatation has begun, when the ankles become ædematous, respiration embarrassed, and the kidneys inactive, I have witnessed marked relief follow the exhibition of sparteine. The action of the heart has become more steady and forcible, an augmented flow of urine has taken place, and the dropsy has lessened. Sparteine is of service in cases of dyspnœa, palpitation, and cardiac debility arising from an excessive deposit of fat around the heart. This is a frequent occurrence in obese individuals, and may be associated with actual fatty degeneration. These patients are subject, after moderate exertion, or in consequence of digestive disturbance, to paroxysms of breathlessness and palpitation, which are very distressing and which excite great alarm in the subject of the attack. Speedy relief follows the use of sparteine in such cases. In dilatation from valvular disease I often give the remedy hypodermically. Good results follow the use of this remedy in functional diseases of the heart caused by excessive bodily or mental labor, anxiety, etc. It has proved useful likewise in the treatment of tobacco heart. As sparteine increases the elimination of urea, it is beneficial in chronic parenchymatous nephritis, being efficient in reducing the dropsical effusions and in preventing the accumulation of urea in the blood. I have frequently, in such cases, maintained the use of sparteine systematically for a considerable period with decided benefit, and without witnessing any ill effects upon the digestive functions. In short, I consider the sulphate of sparteine an excellent drug in any form of cedema of cardiac or renal origin."

Dr. Roland G. Curtin, of Philadelphia: "It has the effect of increasing vascular teusion, which makes it inapplicable in degenerative weakness of the cardiac walls; it is also injurious in obstructive pulmonary diseases—such as pneumonia, hypostatic congestion, etc. It is not as good a diuretic as digitalis or strophanthus or caffeine and some other cardiac tonics. In some cases it seems to act as a diuretic, other times no such action is noticed, and still even frequently it diminishes the quantity of urine. It is rather slow in its action and the effects are rather evanescent, requiring more frequent dosage than some of the tonic medicines usually used for the heart. It can be used

hypodermically better than some other like \*remedies. It is usually well borne by the stomach, better so than digitalis or strophanthus. Eichhorst says that sparteine sulphate stands low in the list of heart tonics, and that it seems particularly applicable in cases of cardiac asthma."

Dr. John E. Bacon, of Sumner, Wash.: "I have used sparteine sulphate in a number of cases of functional cardiac disturbances from overuse of tobacco, with the utmost satisfaction, the drug producing a firm, regular contraction after a few doses of a fourth of a grain each, and invariably slowing the normal number of pulsations per minute. I have used the drug in but two extraordinary cases. From clinical observations and from some experiments that I have been conducting, I believe sparteine to be superior to any drug in common use as a prompt stimulant."

From the foregoing clinical evidence it is seen, then, that sparteine is a medicament of considerable power as a cardiac and renal stimulant, second only, it appears, to digitalis. It is adduced also that sparteine possesses the peculiar advantage of not exerting a cumulative action, although one observer, Bruen,\* believes that it has such an action

I think it would be unnecessary for me to offer any explanations as to the manner in which the drug under consideration acts in the diseased conditions mentioned. Its direct physiological influence on the heart, and its power to enhance the activity of the kidney as a result of the general increase of the blood-pressure produced by the agent, are sufficiently clear.

Sparteine does not produce, as a general rule, any alarming ill after-effects. In all the literature at my command I have found recorded only a few cases of poisoning caused by the drug. One case t was that of an old woman who, after taking a decoction of the tops and seeds of scoparius, vomited and sweated profusely, staggered, and suffered from disturbance of vision. Another case is reported by Prior I in which, after a dose of thirty grains, arrhythmic action of the heart, nausea, giddiness, and a sense of weight in the limbs, were noticed. A third case is published by Bruen, who observed paresis, amounting to paralysis, following the use of the remedy. It is true, again, that Legris, quoted by Wood, | states that headache, vertigo, palpitations, and tingling in the lower extremities were observed after large doses, and that Garand A affirms to have noticed loss of motor power in the lower extremities, redness of the face, and cardiac pain, following the ingestion of the drug. All these symptoms, however, have not been necessarily alarming, much less fatal.

The medicament is perhaps best given by itself, though it may be advisable sometimes to administer it in combination with other remedies. In this connection it may be well to bear in mind the idea of incompatibility. I find that Julliard  $\Diamond$  calls attention to the fact that sparteine and iodide of sodium are incompatible.

Another important point is that of dosage. In this matter authors differ materially. Thus Sée puts down the dose of sparteine as two grains (0:13 gramme) a day; Prior, from a sixth to a third of a grain (0.01 to 0.02 gramme) several times a day; Clarke gave it in amounts of a sixteenth of a grain (0.004 gramme) every four hours, and increased it to twelve grains (0.78 gramme) a day without causing toxic effects. Gluzinski recommends the remedy in doses of from a third to three quarters of a grain (0.02 to 0.04 gramme), while Levaschew has given it in from a grain and a half to four grains and a half (0.09 to 0.29 gramme) three or four times a day. As has been noticed, Tyson employs it also in comparatively large quantities—that is, a fourth of a grain (0.015 gramme) every two hours, or half a grain (0.03 gramme) every four hours. I myself have given sparteine in as high doses as half a grain (0.03 gramme) every three hours. I believe in this energetic method of administration. There is no doubt that large quantities must be used in order to insure the good effects of sparteine; small doses generally lead to disappointment.

1320 AVENUE E.

## REMOVAL OF A NASO-PHARYNGEAL TUMOR BY THE GALVANO-CAUTERY ÉCRASEUR.

WITH EXHIBITION OF CASES.\*

By R. P. LINCOLN, M. D.

Through the invitation of your chairman, I have an opportunity to demonstrate by a case now under treatment a method for the removal of naso-pharyngeal tumors first essayed by myself about twenty years ago. Fortunately, by the great and much-appreciated courtesy of another patient, I am enabled to introduce to you the subject of the first of these cases published by me and operated upon in 1875. Both can be examined after the reading of the paper. The striking correspondence of these two cases, the first and last of a considerable series of a disease comparatively rare, is most unique. The detailed description as published of the first at the time of its removal would serve for an accurate account of the last when, January 12, 1894, the operation was made:

Mr. C. P. B., Jr., aged nineteen years, consulted me in July, 1893, accompanied by his family physician, Dr. Hedges. He complained of headache and obstructed nasal respiration on the left side, which was first noticed in September, 1892. There was also pain in the left eye.

On inspection, the left side of his face was fuller than the right, and the eye of this side apparently more prominent. On examining the interior of the left nostril, an obstruction could be made out about three inches from the tip of the nose, homorrhage from which was started when delicately touched by a probe. Air could not be forced outward through this nostril, but by a strong effort it could be drawn in through it. On the right side nothing abnormal was discoverable; ingress and egress of air could here be made with a slight effort.

Posteriorly, the mirror disclosed and the finger detected a

tumor attached to the vault of the pharynx, principally on its left portion over the upper part of the pterygoid process forward into the left posterior naris. It was elastic to the touch and of a pale purplish color.

The fullness of the left cheek was caused by the presence of an abnormal body near the mucous membrane and prolonged from behind the anterior portion of the zygomatic arch. It was elastic and its dependent portion movable when seized between the fingers, one grasping inside the cheek and the others outside, and susceptible of being crowded upward.

It was doubtless a prolongation from the main body of the tumor at its attachment to the body of the sphenoid, extending through the spheno-palatine foramen. That was my judgment in the first case I reported. Nélaton reports a similar complication in a patient operated on by him.

I advised immediate removal by means of the galvanocautery écraseur, and subsequent repeated cauterization of the stump by the galvano-cautery and electrolysis. Arrangements for a journey around the world had already been made, and the patient's friends decided not to abandon it. Six months afterward the patient again presented himself, mentally happy in the recollection of his coveted trip, but depressed at the contemplation of the growth of his cruel enemy. The tumor had quadrupled in size and all its symptoms increased proportionately, There was no longer any nasal breathing. A profuse mucopurulent discharge flowed from both nostrils. The lower portion of the tumor could now be seen extending a little below the free border of the soft palate and distending it; it was eroded and often bled. The prominence of the left cheek had increased so that its mucous membrane was often pushed between the upper and lower sets of teeth and bitten.

The general physical condition was fair, so that on January 12th I carried out the operation in detail as previously described.\*

In the presence of Dr. Goodwillie, Dr. Miller, and Dr. George Wright I operated at St. Elizabeth's Hospital. The paient being etherized, a double electrode, armed with a looped irido-platinum wire, was passed through the left nostril, the loop being carried into the mouth and behind the tumor up to its attachment.

The connections to the battery being properly made, the tumor was divided at its base in a few seconds, and removed through the mouth with little hæmorrhage.

Every symptom of obstruction was at once relieved and remains unimpaired.

I offer for your inspection the tumor, though much shrunken by having been kept in alcohol.

I am indebted to Dr. Eugene Hodenpyl for a report of the microscopical appearance of the specimen concurred in by Dr. Prudden: "It is composed of rather loose fibrous tissue in which are found a very large number of larger and smaller blood-vessels. The diagnosis is, therefore, vascular fibroma."

The patient made a very quick recovery from the effects of the operation and was able to resume his studies about a month later.

The tumor that presented in the cheek has already somewhat lessened in size. This manifestation deserves further consideration. It is a most interesting and important question whether the experience of the first case—its complete disappearance by atrophy—will be again repeated

<sup>\*</sup> Read before the Section in Laryngology of the New York Academy of Medicine, March 28, 1894.

<sup>\*</sup> Trans. of the American Laryngological Association, 1879.

in this last. The present indications are that our hopes will be realized.

I have only made one cauterization of the stump, because pain in the left eye was much increased in consequence.

It is proper here to state that pain in the eyes long ante dated naso-pharyngeal symptoms and was aggravated by study. The increase of this distress led me to request a renewed examination and report by Dr. J. B. Emerson, the oculist, who has for a long time directed their treatment. I quote the result of his tests: "The fundus of the eye is normal; there is no limitation of movement of eyeball; slight exophthalmus, but nothing detected to indicate a growth in the orbit; there is no explanation of the pain in the eye except that it is reflex or due to astigmatism; has mixed astigmatism." This report was of an examination made the 13th inst. and confirmed yesterday.

Dr. H. D. Noyes also examined the patient yesterday, reaching substantially the same conclusions.\*\*

# THE PRACTICAL WORKINGS OF THE NEW LAWS FOR THE STATE CARE OF THE INSANE.

BY CARLOS F. MACDONALD, M. D.,
PRESIDENT OF THE NEW YORK STATE COMMISSION IN LUNACY:
PROFESSOR OF MENTAL DISEASES IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE;
LATE LECTURES ON INSANITY IN THE ALBARY MEDICAL COLLEGE.

(Concluded from page 621.)

Under the head of occupation, Superintendent Andrews reports: "During the year we have increased the facilities for the employment of patients by fitting up a general workshop in which are now concentrated the industries of the hospital: as the tailor and shoe shop, the making of brooms and brushes, the picking of hair and manufacturing of mattresses, the reseating of chairs, and upholstering.

. All of the clothing for patients is made in the institution, and at less prices than were paid to the prisons for inferior articles. The shoemaker, by the assistance of patients, makes all of the shoes and slippers used by the men and women patients at a reduced cost."

In another part of this report Dr. Andrews states: "During the year we are able to report progress in the improved care given to patients. They have been better fed, better clothed, and made more comfortable and contented. These results have been attained by the increased productiveness of the farm and garden, and by the manufacture of shoes and clothing to the measure of the individual patient, and by a more thorough individualization in treatment. Employment adapted to the ability of the patient and night attendance upon a larger number of the wards have lessened the amount of sleeping remedies given and decreased the noise, violence, and destructiveness both by day and night.

"The change from the former condition is particularly noticeable on the disturbed wards, even to the casual observer, and much more so to those interested in the management. . . . The State Commissioners in Lunacy have made the visits required by law and inspected the conduct of the hospital in all of its departments. They also gave a hearing to all of the patients who desired it and made suggestions looking to the improvement of the service."

The superintendent of the Buffalo State Hospital, in his report for 1893, says: "There have been such changes in the treatment of insanity as have revolutionized our institutions and added immeasurably to the comfort of their inmates. These are epitomized in the change of designation, now so common, from asylum to hospital. All the institutions, by whatever name called, are conducted as places for the care and cure of the sick, rather than for mere retention of the insane.

"The improvement in construction consists in the erection of hospital and infirmary wards where the sick and helpless can receive the care demanded for their condition: the building of amusement halls, of chapels detached from the main structures, of work rooms for the employment of patients; of associate dormitories and dining rooms, of homes for convalescents; cottages for farm hands, colonies, and lastly, as comprehending these various structures, the cottage plan system. All of these changes from the former conventional plan of institutions indicate readiness to adopt such new ideas as give promise of better care of patients." And again: "The increase in the number of physicians and attendants employed in the care of patients, and the higher qualifications required by civil-service examinations, and by the establishment of training schools in most of the State institutions are elements of progress of paramount importance in the conduct of asylums. . . . The extension of night service rendered possible by the erection of large associate dormitories, and by the increase in the number and the better training of nurses, has had the effect to reduce suicides and escapes, to correct the personal habits of the insane, and to remove many of the unpleasant features in their care. The wider range of employment and occupation which is now granted and urged upon our patients is a most potent factor in their treatment. The systematic use of amusements and recreation and the greater liberty allowed to patients must not be overlooked in recounting the forward movement of practical progress. . . . This condensed summary of progress in the construction and administration of hospitals for the insane points to the fact that the real bases of improvement have been, in the main, in the direction of individualization of treatment and in the greater confidence in patients and liberty granted to them. The whole history of the cure of the insane is a striking commentary on the advance of the world in civilization and humanity. . . . We are glad to report an advance in this direction by the action taken by the Commission in Lunacy in the State of New York, who recently issued a circular authorizing the managers of State hospitals to permit the introduction of students under proper restrictions to the wards of the various institutions. This furnished an opportunity for all the colleges to give

<sup>\*</sup> During the discussion that followed, Dr. Noves stated that his opinion, expressed in a letter twenty-four hours before, had been modified, and that his present judgment was that a tumor had intruded into the orbit and that its pressure on the eyeball gave rise to certain ocular symptoms.

to their students long-desired instruction upon this subject. Favorable action was taken by the managers of the Buffalo State Hospital, and during the winter months clinical instruction was given on the wards to the students of both of the medical colleges of the city. This is a step of progress which it gives me great pleasure to report."

The superintendent of the Utica State Hospital, in his report for 1892, in speaking of the new buildings erected under the State Care Act, says: "One can not commend too highly this new provision for the feeble, demented insane of the chronic class. Associated as they are in large, lofty, airy day rooms and dormitories, with structural arrangements and conveniences adapted to their helpless condition, it is now possible to care for them with a minimum of inconvenience and the maximum of efficiency. . . . The infirmary has a separate day and night service. The work of the day attendants is taken up by those of the night, and pursued with the same careful regard to conditions of cleanliness, so that good habits have been created even in cases where the attempt at rescue from degradation seemed almost hopeless. As a concrete example of what has been done under the new régime, I may mention the striking fact that where formerly in the main building half of the number of women patients of the same class soiled as many as seventy-five sheets per night, the number reported in the new building for women has frequently been naught."

This same report under the head of occupation says:

"At the risk of appearing a faddist on the subject of occupation, I venture to say that in no respect has the general weal of our patients been more manifestly promoted than by the increased avenues of employment that have been thrown open to them." This report concludes with the following striking paragraph:

"We approach the new year with better facilities for the care of the insane than have ever before been ours. Ours will be the fault if we do not to the utmost avail ourselves of our opportunities to fulfill the promise and discover the potency of the epoch-making enactment of 1890."

The report of the superintendent of this same hospital for 1893 says: "The general health of the house has been good, and one may in reason claim that, on the whole, our people have been comfortably housed, fed, nursed, and clothed. As regards creature comforts generally they have by no means fared ill."

And again, in referring to the improvements and betterments made to the buildings during the year: "All this new work of which you (the managers) make mention in your report will vastly add to our facilities for carrying out the objects of the institution and promoting its efficiency."

The managers of the St. Lawrence State Hospital in their report for 1893 state: "This hospital presents a history of steady and unchecked growth since its creation by statute, and the past year contrasts favorably with previous ones in this respect." The superintendent of this hospital, in his report for the same year, referring to the completion of a new group of buildings, says: "It stands now an ideal asylum building for the care of four hundred insane women

of the class not strictly requiring active hospital treatment or infirmary care. There can be no doubt that it will fulfill its purpose in an admirable manner."

The superintendent of the Hudson River State Hospital in his annual report for 1893, in reference to increasing the capacity of the building by utilizing the sitting rooms as dormitories, says: "The use of the three sitting rooms as dormitories has worked no hardship to the patients. as there is ample day space in the large corridors and double alcoves. In fact, the change has resulted in an improvement in the appearance of the corridors, for they have been made more cheerful by the addition of furniture and pictures. But the greatest advantage has been in the improvement in the night care of the helpless and filthy, which is made practicable by the fact that the new dormitories are in close proximity to the water section. The use of the objectionable chamber vessel is avoided and habits of cleanliness are cultivated by the regular and systematic attendance of the night nurses, which only such an arrangement can make possible. . . . Thus without undue crowding the permanent capacity of the hospital has been increased by three hundred and two beds. A building to accommodate a like number under the State care allowance would have cost the sum of \$166,000. The relief which was thus obtained was very great, and was appreciated by officers, nurses, and patients. . . . The pictures and furniture purchased during the past year have added greatly to the appearance of some of the wards; but we have only made a beginning and can not keep on without more funds." And again: "The several members of the State Commission in Lunacy have made frequent official visits during the past six months, and I am indebted to them for many practical suggestions in regard to the details of hospital management. Their visits and inspections are a spur to every medical officer and to the nurses as well. When it is remembered that they are constantly going from one hospital to another, gathering the best points in the management of each, it is evident that the recommendations which they make should tend to greater efficiency in the management of all."

The managers of the Hudson River State Hospital, in their report to the Legislature for 1893, state: "With the additional beds that have been provided the capacity of the hospital is now 1,400—750 in the men's department and 650 in the department for women."

In view of the allegation recently made that the policy of the commission in lunacy has resulted in seriously over-crowding the Hudson River State Hospital, it is proper to state in connection with this subject that the present number of inmates of this hospital (February 1, 1894) is 710 men and 635 women, a total of 1,345 patients, or 55 less than the capacity of the hospital as certified to the commission by the managers.

The managers of the Rochester State Hospital, in their annual report to the State Commission in Lunacy for 1893, say: "The unsatisfactory condition of the buildings, noted in our first annual report, has been removed to a considerable extent, and it has been demonstrated that the thorough renovation recommended at that time can be carried out successfully and economically."

"In accordance with plans and specifications prepared by J. Foster Warner, architect, in conformity with the recommendations of the State Commission in Lunacy and Architect I. G. Perry, an administrative department and a new department for male patients have been constructed, within the amount appropriated therefor. The crowding which we so strongly deprecated in former reports is thereby relieved and the comfort of the patients largely enhanced."

In this same report the superintendent of the hospital says: "Through the liberality of the State Legislature the managers of the Rochester State Hospital have been enabled to build and furnish, at a per capita cost of \$550, four large, well-lighted, cheerful wards, with dormitory and lavatory accommodations, and an administrative building, with comfortable apartments and convenient offices.

"A large embayed extension has been built in connection with wards four, six, and eight in the female department, which adds much to their attractiveness. Verandas, that command a wide and beautiful view, have also been added to these wards."

Surely there is nothing in the foregoing extracts from the reports of the State hospitals which would justify the assertion recently made that these institutions "are rapidly deteriorating as curative institutions."

It has also recently been asserted that the State hospitals are being greatly overcrowded. It should be borne in mind in connection with this subject that there is scarcely a public hospital or asylum for the insane in this or in any other country whose annual reports do not from time to time teem with complaints of overcrowding, and whose superintendents do not frequently cry out for relief in this matter. Certainly this has been true of all hospitals and asylums in the State of New York for the past thirty years, until overcrowding came to be regarded as a normal condition. When the Lunacy Commission began its official work it found, in the Utica State Hospital, patients uncomfortably housed in an abandoned chapel, in the fourth story of the administration building, also in the barren attic of an outbuilding. At the Middletown State Hospital it found a considerable number of patients crowded into the attic of the administration building, while at the same time there were instances of private patients who were provided with a suite of rooms and two private attendants, each of whom occupied single rooms. In one of the buildings of the Binghamton State Hospital nearly a hundred patients of the most disturbed and violent class were crowded into a dark, dilapidated, and unwholesome basement, which, as regards noise and violence, was the nearest approach to the ideal "bedlam" that the writer has ever seen in this or in any other State or country. Suffice it to say that the use of these places as receptacles for insane patients has, in each instance, been abandoned, and their former occupants are now all comfortably housed in suitable and proper quarters. And this, notwithstanding the fact that, in obedience to the duty imposed upon it by the State Care Act, the commission has removed from the poorhouses, where they were in a condition of wretchedness, squalor, and neglect, in round numbers, two thousand patients, to the custody of the State,

where they are now comfortably housed, fed, and clad, and provided with proper medical supervision and care, thus accomplishing, within a period of three years, the work that all efforts in that direction during the past thirty years had failed to accomplish. The work of rapidly transferring to the care of the State this large number of insane poor necessarily involved some temporary embarrassment and discomfort to the State hospitals, but it is gratifying to say that, except in two or three instances, the officials of these hospitals have cheerfully co operated with the commission in carrying out this delicate and difficult duty, realizing that the discomfort was a necessary incident to the change of methods and that it would rapidly disappear when the transition state was passed.

Regarding the statement which has recently been put forth, that there is a growing sentiment averse to the Lunacy Commission, and that the whole procedure of the commission is tending to convert the State hospitals into immense pauper establishments; that these institutions are rapidly deteriorating as curative establishments, owing to the lowering of the standard of care and overcrowding of them by the commission, the statement is not sustained by the facts. On the contrary, since its creation down to the present time, the commission has constantly had the confidence and support of the Chief Executive, of the State Comptroller, and substantially of all of the members of both Houses of the Legislature, regardless of party, while its work has been officially commended by most of the hospital managers and by a large majority of the medical officers of both the public and private institutions for the insane, as well as by the State Charities Aid Association, whose report on the dependent insane and the administration of the laws relating thereto, for 1893, contains the following: "It is, however, fully aware that good laws, badly administered, often fail of their purpose, and it is, therefore, with pleasure that we now place on record our belief that these laws have been ably and fearlessly administered by the State Commission in Lunacy."

By the act of 1893, which provides for the support of the dependent insane by the State, and which went into effect on October 1st last, the Legislature put upon the Commission in Lunacy the responsibility of a general supervision of the expenditures of the State hospitals. The law requires the hospital authorities to present to the commission each month an itemized estimate of expenses for the coming month. These estimates the commission is required to scrutinize, and is empowered to revise, as in its judgment seems best, whether as regards quantities, qualities, or prices of supplies, the object of the law being to place upon some central and independent body the duty of regulating the expenditures of the large sums of money which, under the State Care Act, require to be annually appropriated by the Legislature for the care and treatment of the insane.

The commission, with a full sense of its duty to the welfare and comfort of the dependent insane on the one hand, and of its responsibility to the taxpayers on the other, entered upon the work of passing on the monthly estimates with the beginning of the fiscal year, October 1,

1893. This involved the originating and putting into practical operation of an entirely new financial system for the State hospitals, and was, of course, a radical departure from the old methods of expenditure and of accounts, the funds received by the State hospitals from counties, private patients, and from other sources having hitherto been expended by the superintendents of these institutions in their discretion, subject only to approval and audit by the local boards of managers.

Under the former system, which had been in operation for many years, many abuses naturally grew up, and it is a fact that in at least three of the hospitals great extravagances have existed. It should be said, however, that this statement would not apply to all of the State hospitals, as certain of them are believed to be very carefully conducted as regards their expenditures, as well as in the matter of discipline and the medical care and treatment of their inmates, so that any general or sweeping criticism unfavorable to the State hospitals as a whole would be manifestly unjust. The recent investigation of the management of the Hudson River State Hospital revealed, as the printed testimony shows, a most shocking state of affairs. The per capita cost of maintenance in that institution was shown to have been much higher than that of any other State hospital, while the rate of recovery and standard of care generally was far below that of the other hospitals. The institution was disorderly and demoralized, and great extravagance and looseness in methods of expenditure and in the auditing of bills was found to exist. These facts were substantially admitted by several members of the board of managers, who professed ignorance of them on the ground of inattention on their part. It is proper to state that under the new superintendent this hospital is rapidly being brought up to a high standard of efficiency.

The commission, since October 1, 1893, when it began the work of supervising the expenditures of the State hospitals, has endeavored to curtail expenses by lopping off what it regarded as clearly improper and unnecessary items of expense, and also by disallowing certain other expenditures which, in its judgment, could not properly be charged to the maintenance fund. In numerous instances, however, the commission has increased the sum of the estimates by insisting on the purchase of a better quality of supplies than was called for by certain of the hospitals, notably in the matter of tea, coffee, flour, meats, stimulants, clothing, and blankets. In its efforts to reduce the financial system of these hospitals to a business basis and put a proper check upon expenditures, it was inevitable that the commission should encounter criticism and even hostility on the part of those whose pet methods it had interfered with, not to speak of the ill-will of certain local tradesmen whose profits were doubtless largely diminished. It would also be surprising if, in establishing a financial system of such vast magnitude and immense detail, and involving such widespread interests, the commission should not have made mistakes in minor matters and should have succeeded in completely avoiding friction with hospital authorities, especially in the organizing stage of the new system. The superintendent of the Utica State Hospital, in his report

already referred to, says: "The transition from the old order of things to the new will not be accomplished without friction. Soon, however, the machinery must adjust itself to the new requirements. And surely one may safely leave the future to take care of itself, if, in meeting the new problems that will arise, we pause to ask ourselves the simple question whether the end we have in view is the application to our everyday work among, and in behalf of, the insane of the humane principle that underlies the State Care Act, and which alone made its passage possible."

It should be borne in mind that the commission does not originate the estimates, but simply revises and approves them, and that superintendents are free to insert in their estimates any proper item of expenditure. Neither does the commission disburse the funds for these expenditures, as has been alleged, nor does it direct where these expenditures shall be made. It has, however, endeavored to enforce the policy of having staple articles of food supply for the hospitals, such as flour, sugar, tea, coffee, coal, etc., purchased in bulk for all the hospitals and at wholesale rates, the purchases being negotiated for by a committee of the superintendents themselves, and in this it believes it will be sustained by the business sense of the community and by the medical profession as well. Nor is the commission interested in securing the trade of these hospitals to any particular dealers or class, and any statements to the contrary are absolutely and unqualifiedly false. Furthermore, the writer unhesitatingly asserts that the true explanation of the animus toward the commission which is now being manifested by two or three of the hospital superintendents and their managers is to be found in the fact that the new system of supervision of expenditures by an independent body deters these superintendents from inserting in their estimates items for the purchase of grossly improper and extravagant articles for their own personal use, purchases which, under the former system, they have been free to make without let or hindrance.

Vouchers of at least three of these hospitals on file in the State Comptroller's office show a most lavish expenditure for themselves and the entertainment of managers and friends, while at the same time supplying patients with a low grade of food supplies, including the quality of beef known as "chucks" and "necks" at four cents a pound, fish at two cents and a half to three cents a pound, also inferior, adulterated foods, especially tea and coffee.

The commissioners realize that the people of the State are abundantly able and willing to provide everything that is essential for the proper care and treatment of its dependent insane, and they have determined that these unfortunates shall not be denied any of these essentials; but they would be recreant to their trust and to their oath of office if they failed to promptly check to the full extent of their powers any tendency which they may discover in the direction of extravagance, improper expenditure, or misapplication of the public funds.

In concluding this branch of the subject it may be said that a careful estimate of the expenditures of the State hospitals under the new system, including everything that is proper and necessary to be supplied out of the public funds, will show that a large annual saving to the taxpayers of the State, aggregating at least \$250,000, will undoubtedly be effected.

Respecting the allegation which has recently been put forth that the commission has prohibited the use of tobacco in the State hospitals, it may be said: The commission has made no order forbidding the use of tobacco in these institutions. It has simply disallowed the items for that article in the hospital estimates. So far as action by the commission is concerned, the inmates of the State hospitals are not prohibited from using tobacco, except at the expense of the State. It is a fact that a large proportion of these patients obtain tobacco from their friends, from employees, and from visitors. In fact, it is practically impossible to abolish the use of tobacco absolutely in hospitals for the insane. The action of the commission has merely tended to minimize the abuse of tobacco chewing in State hospitals, which was a very serious one, as many patients without sufficient mentality to exercise a rational judgment in the use of tobacco have simply saturated themselves with it, and cases of tobacco poisoning are not infrequent. Repeated instances have occurred of patients drinking the tobacco expectoration from the cuspidors and extracting the quids of tobacco from these receptacles and chewing the same. Furthermore, observation has shown that many patients have acquired the tobacco-chewing habit after admission to the hospital, and certainly it is a serious reflection upon the management of a hospital for the insane to have patients acquire a habit of this kind while in their custody and care. Instances of young adults who have become addicted to tobacco chewing after coming to the hospitals are very common, and the proportion of tobacco chewers to the population in asylums is very greatly in excess of that in the sane population outside, so far as it can be approximately determined. Moreover, experience has shown that wherever the practice of issuing tobacco to patients in hospitals for the insane has been discontinued, it has been attended with most satisfactory results, as attested by the testimony of Dr. Cronyn, president of the Board of Managers of the Buffalo State Hospital, who abolished the use of tobacco in an asylum for the insane of which he was formerly superintendent; of Dr. A. E. Macdonald, the general superintendent of the New York city asylums for the insane, in which the use of tobacco was abolished in 1874 and has never been renewed; and of the writer, when superintendent of the Auburn State Asylum, in which the practice of furnishing tobacco was abolished in 1880.

It would be easy to show that the unrestricted use of tobacco, which has heretofore obtained in several of the State hospitals, has resulted in marked demoralization and filth in the wards, and in numerous cases has directly aggravated mental conditions, especially those of an irritable form, tobacco being a direct irritant to the heart.

Regarding the use of tobacco in the New York city asylums for the insane, Dr. A. E. Macdonald, in a letter under date of November 6, 1893, says: "In answer to the inquiry of your commission regarding the use of tobacco in the city asylums, I beg to say that such use was discontinued shortly after my appointment to the City Asylum, by the fireman in order that he might not be short of help.

Ward's Island, in the fall of 1874. I found, upon assuming duty there, that tobacco was issued indiscriminately by the warden, matron, and other lay officers, without any reference to the physicians; that its use was either for the purpose of securing special work or in order to pacify patients who threatened disturbance or violence unless tobacco was given to them.

"Much turbulence and quarreling among the patients was caused by this distribution-stronger patients forcing weaker to give them their share of the distribution-and in some instances serious trouble was caused by tobacco poisoning through the swallowing of the tobacco by demented patients; at the same time the effect upon the discipline and cleanliness of the asylum was markedly unfavorable.

"The abandonment of the use of tobacco has not resulted unfavorably in my experience; on the contrary, there has been a decided improvement in the condition of the patients and of the buildings.

"I do not think that the deprivation of tobacco causes any greater distress to individual patients than the deprivation of liquor or other indulgences to which they have been accustomed, and I see no good reason for its general use or distribution.

"If tobacco is to be used at all in asylums, I should favor its use only by convalescent or chronic cases, who might be rewarded for work by being permitted to smoke in places and at times specially designated for the purpose. I should not advocate its being issued indiscriminately or for use otherwise."

Dr. H. G. Matzinger, of the Buffalo State Hospital, writes as follows regarding the use of tobacco in that institution: "During your last visit here you requested me to write you my experience with the use of tobacco among insane patients, and my opinion of the effect of its discontinuance.

"In nine cases out of ten the chewing habit led to uncleanliness of greater or less degree, according to the personal habits of the patient. His face and clothing always bore ample evidence of its use, often to a nauseating degree, and his idle hours were spent in filling spittoons, from which it was not uncommon to see other patients take the guids and chew them.

"In many cases the habit of chewing was acquired by begging a sufficient quantity, and so the demand grew, and the friends were importuned to bring it, if refused by the physician. When it was the custom to reward some patients for work or to induce them to work by offering tobacco, others soon discovered the fact and frequently objected to doing anything unless they received their share, even though they never used it. It was then traded for other things with other patients, or workmen on the grounds.

"In two cases which I recall now a serious form of tobacco poisoning occurred. One, a negro, employed in the engine room, has had several periods of quite prolonged illness following the immoderate use of chewing tobacco. He exercises no discretion whatever in its use, has periods of irritability when it is difficult to keep him continuously at work, and at such times he was given a larger supply

"The other, a mild dement, was issued his ordinary supply at the end of the week and apparently devoured all of it within a few hours afterward. He was brought to the ward and soon passed into a condition approaching collapse. He was cold, pale, tremulous, and almost pulseless. On inquiry, it was found that he had been eating a large amount of tobacco. He was given a dose of oil and soon passed a black mass of macerated leaves, filling half the vessel. After this the patient gradually recovered his ordinary condition.

"It was quite a common occurrence to have patients suffer from indigestion and headache, due directly to the use of tobacco in quantities to which they were not accustomed.

"On the whole, I do not recall that smoking caused any trouble. It was always done under supervision, and was not allowed on any part of the grounds or in the buildings except in the smoking room of the cottage. It proved a great source of comfort to many aged people and patients who had been accustomed to it for many years.

"When the order of the superintendent to discontinue the use of tobacco, which resulted from an informal discussion of the subject between yourself and the medical officers of the hospital on the occasion of your last official visit, was first put into force, there was considerable objection for a few days, but since then we have experienced no trouble of any kind. Patients are as industrious as before, and no deleterious result has been observed.

"All inquiries on the part of patients and their friends in relation to the use of tobacco are met satisfactorily and finally by the statement that it is not allowed. The interdiction of the general use of tobacco in this hospital has, far from causing annoying unpleasantness, been most gratifying, removing a great source of personal uncleanliness, of dissatisfaction, and of possible injury to health."

Having thus outlined the principal points which have presented themselves in relation to the practical workings of recent legislation for the insane in the State of New York, and having cited from official reports of the hospital managers and superintendents ample proofs of the main position herein taken, namely, that the present laws respecting the insane, as administered, have resulted in marked improvement in the condition, equipment, and management of the hospitals, and in the general well-being of their inmates, while at the same time effecting important economies in expenditure of the State's money, the writer feels that the commissioners in lunacy may justly maintainthat, in their administration of these laws, they have been actuated solely by a desire to promote the welfare and comfort of the State's insane, and, as one of the most efficient means to this end, they have steadily aimed, both individually and collectively, to have the best features in each hospital's work adopted by all the others.

In conclusion, it is gratifying to be able to state that, in its efforts in this direction, the commission has had the cordial co-operation of a large majority of the superintendents and medical officers generally, to whom much credit is due for the measure of success that has been attained.

Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, MAY 26, 1894.

ANIMAL EXTRACTS AND JUICES IN THE TREATMENT OF DISEASE.

SINCE we last discussed this subject some notable contributions have been made to its literature. For example, at a recent meeting of the Société nationale de médecine de Lyon, the proceedings of which are reported in the Province médicale for April 21st, M. Teissier and M. Fraenkel made a report of their researches on the physiological action of injections of a glycerin extract of the kidney in persons affected with albuminuria. They said that these researches had been undertaken at the instigation of the late Professor Brown-Séquard, in order to ascertain as exactly as possible the influence of the renal liquid on the great organic functions, and especially on the elimination of toxic substances by the urinary secretion. They had been carried out with the glycerined extract prepared by M. Jacquet from the substance of the sheep's kidney by carefully triturating it and macerating it for twenty-four hours in a ten-per-cent. mixture of glycerin and water. This preparation is said to be absolutely harmless, and the limits within which the quantity injected may vary are very large; in an animal, for each kilogramme of the weight twenty cubic centimetres may be injected beneath the skin or into a vein without occasioning any unpleasant results or any disturbance of the urinary function. An injection of a hundred cubic centimetres to the kilogramme, on the contrary, gives rise to speedy death with intense dyspnœa, nystagmus, and convulsions. In patients, they injected only two cubic centimetres a day for the first few days, and afterward the same quantity twice a day. Even from such very small doses highly interesting effects had been noticed.

The authors selected two patients, one of whom was affected with typical interstitial nephritis, with ædema, cardiac disturbances, and general troubles connected with urinary insufficiency, and the other of whom had dyscrasic albuminuria. These patients were put upon the use of a strict milk diet for three days, so as not to interfere with the results of the observations. During these three days the urine was fully tested for urea, phosphates, chlorides, etc., and its toxicity was established according to Bouchard's method. The density of the blood was ascertained by Lyonnet's process, and the red and white blood-corpuscles were counted. In this way each patient's nutritive condition was established, the mean of the figures obtained during the three days of observation being taken. This method of observation was pursued for five days, on each of which the renal extract was administered subcutaneously; then for three days no injections were given.

There was no change in the quantity of urine passed. There was no apparent modification of the density of the blood or of its corpuscular composition, but there was a slight increase of the arterial pressure. On the other hand, there were very perceptible modifications of the chemical constitution of the urine and especially of its toxic property. In the patient affected with interstitial nephritis a slight increase of urea was noticed; there was no change in the proportion of chlorides, but there was a marked increase of the phosphates. There was a sensible augmentation of the urinary deposits, together with a heightening of the uro-toxic co-efficient, without the quantity of albumin being modified. But the most important fact noted was the property of producing myosis possessed by the urine passed on and after the second day of the period of injections used in quantities of only sixty cubic centimetres, while during the preparatory period this phenomenon, which is in some sort an index of the degree of toxicity of the urine, did not occur at all or only to an almost inappreciable degree after the use of three hundred and fifty cubic centimetres.

In the second case the results were analogous in the main, although they differed in some matters of detail. The urea suddenly increased from 20'75 grammes to 26 grammes, and the chlorides rose from 5'70 grammes to 9'80 grammes, without change in the phosphates. But the most interesting feature was the disappearance of the albumin during the days on which the injection was practiced, in spite of a higher temperature, and its reappearance after the injections were discontinued. Moreover, as in the first case, there was a considerable rise of the uro-toxic co-efficient.

The most important point in these authors' observations is the establishment of the fact that these injections augment the kidney's power of eliminating toxic substances. Undoubtedly, says the report, this elevation of the uro-toxic co-efficient is to be attributed to the elimination of the substance injected, but its amount is so small as to be lost in the whole amount of urine passed in twenty-four hours. One is inclined therefore to invoke dynamic action favoring the oxidation of the products of disintegration by exciting the secretory faculty of the renal parenchyma, the integrity of which is perhaps necessary for elaborating the toxic substance to be eliminated. Finally, the feeling of general amelioration experienced by the patients during the use of the injections is to be mentioned. As a result of their physiological action and their harmlessness, thus demonstrated, the use of these injections seems to the authors to be warranted in the treatment of nephritis. As a matter of fact, M. Teissier has already used them with advantage in a certain number of cases.

The general subject of the use of organic extracts and juices in therapeutics was made the topic of discussion at a recent meeting of the Gesellschaft für innere Medicin, of Berlin, a report of which we find in the Gazette médicale de Paris for April 28th. Dr. Fürbringer is reported as having maintained in this discussion that the method acted mainly by suggestion. In his practice no good results had been obtained by the injection of testicle juice. Moreover, the favorable cases,

those in which benefit had been obtained in the treatment, he said were rare and did not prove the antidotal virtue of the medication. The speaker remarked that Pohl regarded spermine as a vital principle scattered through the entire organism; therefore the introduction of spermine into the system would be indicated when the elements of the economy contained it in smaller quantity than normal. It was in conditions in which oxidation was imperfectly performed that spermine found its indication. While the speaker was thus severe on testicle juice, he admitted the superiority of the treatment of myxicdema with thyreoid extract. Pancreatic juice employed as a remedy for diabetes, he said, had not yielded brilliant results. Vitaline, a compound of several extracts, was often employed in Russia, but the statistics of cases treated by its use were not encouraging. American practitioners and Onimus, of Monaco, had spoken highly of cardine, obtained by macerating the heart of a bullock for eight months; the results obtained seemed to be remarkable. Brown-Séquard and Dieulafoy had experimented with nephrine in diseases of the kidney, and had proclaimed its good effects. Finally, said the speaker, except thyreoid extract and possibly Pohl's spermine, the organic extracts should not yet be used outside of the laboratory. The clinician's function consisted in distinguishing between what was really due to the medication and what was produced by suggestion.

Dr. Goldscheider followed with an account of his lack of success in the use of various animal extracts and juices. He admitted, however, that Brown-Séquard's theory rested on a scientific principle, but thought that thus far its practical application had necessarily been more or less haphazard. Not until physiology had tried and determined the essential elements of each extract, he concluded, could the organic liquids be considered as of much assistance in therapeutics.

#### ETHYL BROMIDE AS AN AN. ESTHETIC.

In the Journal des praticiens for May 2d there is an article on this subject by M. Eloy, who says that there is at the present time a movement in favor of this drug as an anæsthetic, and physicians are therefore interested in knowing when and how to use it. The chemical purity of the drug, he says, may be ascertained by the following characteristics: It is a colorless liquid, refracting and dense; the odor is like that of chloroform; it has a burning taste, and boils at 100.2° F. or 102.1°. It is insoluble in water, soluble in alcohol, in ether, in chloroform, and in oil; it is slightly inflammable, and, as it decomposes on exposure to air, light, or dampness, it should be kept in yellow bottles carefully corked.

Ethyl bromide possesses very useful physiological properties. When inhaled, it produces narcosis in two stages. The first is that of partial anæsthesia with full consciousness; the sensibility and the perceptions become deadened, and there is little or no trouble with the respiration or the circulation. In the second stage there is anæsthesia with loss of consciousness, trembling of the muscles, and dilatation and insensibility of the pupils. There is no perceptible alteration in the pulse; there is

a slight change in the blood pressure, and there is very little cardiac disturbance. According to Bottinger, ethyl bromide does not change the blood; it spares the corpuscular elements of the blood and is rapidly eliminated by the lungs, the skin, and the kidneys. Its action is powerful and, above all, rapid. Narcosis follows its administration in from thirty seconds to a minute, and is kept up by inhalations repeated every minute for about ten or fifteen minutes, beyond which time it is dangerous to continue the inhalations. During this procedure there is no suffocation or cyanosis, and the features do not change. On the patient's awakening, there is a prompt return to the normal condition, and there is very rarely any vomiting, headache, or contraction of the pupils. With regard to these phenomena, M. Pouchin attributes the anæsthesia of ethyl bromide to an unknown action on the nervous centers. According to Lewis, ethyl bromide can not be used in long operations, as the anæsthesia is of short duration; neither can it be used where the loss of blood is likely to be considerable, as it may increase it. These are the physiological contraindications to its employment. The clinical contraindications, according to Sternfeld, are pulmonary tuberculosis, acute and chronic bronchitis, pulmonary emphysema, cardiac disease, pronounced anæmia, and hysteria; also, according to Gunsburg, alcoholism.

Ethyl bromide may be taken internally in doses of five or six drops in water, or in capsules, or in solution in alcohol. The inhalations produce an insensibility which is useful in small operations, such as incision of superficial tumors, of the skin, and of the mucous membranes, etc.; it is useful also in dentistry and in obstetrics, where it is applied in the same manner as chloroform in normal or complicated confinements. It may be employed before chloroform inhalations as a sort of preparatory anesthesia to shorten the initial stage of chloroform narcosis.

M. Poiton-Duplessy considers that these inhalations of ethyl bromide weaken the laryngeal, nasal, and bronchial sensibility.

With regard to the administration of ethyl bromide, the author remarks that it varies according to the operator and the attendant circumstances. Some physicians produce anæsthesia with ethyl bromide alone, others a "mixed" anæsthesia with ethyl bromide and chloroform. The former is rapid and short, suitable for slight operations; the latter is a preparatory anæsthesia, prolonged and completed by chloroform narcosis for serious operations. The following method of using ethyl bromide is recommended: A flannel mask which has been thoroughly saturated with the drug is applied quickly to the nose and the mouth in order to keep out the air. The face becomes discolored, ocular congestion and muscular relaxation follow, and at this moment the operation should be performed. Contraction of the jaws may take place, impeding the opening of the mouth, and when this resistance ceases the narcosis has disappeared and the inhalations must be repeated. In "mixed" anæsthesia M. Chaboux, of Rouen, uses the following method: 1. Cover the face as far as the chin with a flannel mask having a framework of wire. 2. Thoroughly saturate the flannel with from 150 to 225 grains of ethyl bromide, and repeat this in twenty seconds with the same quantity. 3. Keep the mask on

for forty or forty-five seconds, when slight suffocation, facial congestion, and swelling of the vessels of the neck will take place. 4. Replace the ethyl bromide with chloroform, which is administered by the standard method. In this way a diminution of the normal period of excitation and vomiting is observed during and after the anæsthesia. It would be well, says M. Eloy, for all physicians to interest themselves in the subject of ethyl bromide as an anæsthetic.

#### MINOR PARAGRAPHS.

THE SANITARY REGENERATION OF HAMBURG.

Some months ago we published a communication in which it was shown that the sanitary condition of the city of Hamburg had been maligned during and after the cholera invasion of the summer of 1892. In the forthcoming June number of the Atlantic Monthly, for an advance copy of which we are indebted to the publishers, Messrs. Houghton, Mifflin, & Co., there will be found an exceedingly interesting and instructive article entitled Hamburg's New Sanitary Impulse, by Mr. Albert Shaw, of the Review of Reviews. Mr. Shaw shows abundantly that in everything but its water supply Hamburg was in a condition in the summer of 1892 that was not open to serious criticism from a sanitary point of view, and that, as to that one particular even, a magnificent system of filtration of the Elbe water was in process of establishment, although, unfortunately, with its inlet not far enough above the harbor. The works were hurried to their completion, but somewhat too late; the cholera came, with what disastrous results to Hamburg we all know. But out of the nettle danger Hamburg is plucking the flower safety. Mr. Shaw declares that its drinking-water is now perfectly safe and palatable. Incidentally, it is interesting to learn that the new municipal Hygienic Institute is under the direction of one of our own countrymen, now a naturalized German citizen, Dr. Dunbar, a native of St. Paul, Minnesota, whose experiments Mr. Shaw speaks of as of extraordinary interest. We look upon the publication of Mr. Shaw's article in a magazine of general literature as peculiarly appropriate, since it is there more likely to make an impression on the public mind than if it had seen the light in company with only technical matter

## PERUVIAN BALSAM IN THE GASTRO-INTESTINAL DISEASES OF CHILDREN.

This substance, says the Revne mensuelle des maladies de Penfance, was recommended by Trousseau and Pidoux in chronic intestinal catarrh, especially in diarrhœa, with or without tenesmus, in typhoid fever, and in infectious dysentery. Now, according to the same journal, Nuggia has found it useful in the gastro-intestinal diseases of children. He uses a solution of from a grain and a half to three grains of the balsam (for very young children; for older children, from four and a half to eight grains) in a mixture of forty-six grains of alcohol, two hundred and seventy-five of syrup of lemon, and twelve hundred of water. It is to be presumed that this amount is given in twenty-four hours.

CASTRATION AS A REMEDY FOR HYPERTROPHY OF THE PROSTATE.

In the *Centralblatt für Chirurgie* for April 28th Dr. Fredrik Ramm, of Christiania, gives the notes of a case of prostatic en-

largement in which he resorted to this procedure with benefit, and lays down the following propositions: 1. The prostate belongs among the sexual organs. 2. It becomes developed after the occurrence of puberty or simultaneously with it. 3. In cases of malformation of the sexual organs it retains its infantile size, as in cases of castration before the period of puberty. 4. After castration in adults it withers. 5. A hypertrophied prostate shrinks after castration; the process begins at once and goes on increasing. 6. This decrease of the prostate in volume after the removal of both testicles may be turned to account in the treatment of mechanical impediment to urination occasioned by hypertrophy of the prostate.

#### A STRIKING INSTANCE OF FECUNDITY.

The Journal de clinique et de thérapeutique infantiles for May 10th says that a woman forty-nine years old lately presented herself at the Belleville Dispensary with the story that, having been married three times, she had had twenty-five children born alive and two miscarriages at advanced periods of pregnancy. All her sons, nineteen in number, died in childhood, but she has five daughters left, the eldest of whom, twenty-eight years old, is now six months pregnant.

#### THE EXPERIMENTAL PRODUCTION OF MONSTROSITIES.

We find it stated in the Gazette médicale de Paris for May 5th that at a recent meeting of the Société de biologie M. Féré reported that by injecting various microbic toxines into the whites of hens' eggs in process of incubation he had succeeded in producing monstrosities in 58:33 per cent. of the eggs, while in eggs not interfered with the percentage was only four.

#### ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending May 22, 1894:

DISEASES.	Week end	ing May 15.	Week ending May 22.		
DIMENOIS	Cases.	Deaths.	Cases.	Deaths.	
Typhoid fever	7	3	6	1	
Scarlet fever	133	13	136	10	
Cerebro-spinal meningitis	2	2	4	3	
Measles	231	9	162	10	
Diphtheria		70	237	67	
Small-pox		3	11	6	

The New York Dermatological Society.—At the annual meeting, held on Tuesday evening, the 23d inst., officers for the ensuing year were elected as follows: President, Dr. Hermann G. Klotz; secretary, Dr. Samuel Alexander; executive committee, Dr. Charles W. Allen, Dr. John A. Fordyce, and Dr. S. Lustgarten.

The Honorary Degree of Doctor of Laws, we learn from the *Medical News*, was conferred recently on Dr. William Goodell, of Philadelphia, by the Jefferson Medical College.

The Police Surgeons of New York City.—A bill increasing the annual salary of these officers from \$2,200 to \$3,000 has been passed by the Legislature and signed by the Governor.

The Hudson County District Medical Society of the State of New Jersey.—At the annual meeting, held on May 1st, officers for the ensuing year were elected as follows: President, Dr. F. M. Corwin; vice-president, Dr. J. J. Broderick;

secretary, Dr. J. M. Rector; treasurer, Dr. A. H. Brinkerhoff, Jr.; reporter, Dr. J. A. Exton.

Changes of Address.—Dr. Parker Syms, to No. 60 West Forty-seventh Street; Dr. J. F. Terriberry, to No. 120 West Seventy-third Street.

The Death of Dr. Charles James, of Brooklyn, occurred by a shocking misadventure on Tuesday, the 22d inst. In the dark he seized a bottle containing incture of aconite and swallowed a teaspoonful of the contents, instead of a medicine that had been prescribed for him by a colleague. The deceased was twenty-seven years old and a graduate of the Long Island College Hospital Medical School.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 13 to May 19, 1894:

Hubbard, Van Buren, Major and Surgeon, is granted leave of absence for four months, on surgeon's certificate of disability.

Chapin, Alonzo R., Captain and Assistant Surgeon, is granted leave of absence for three months, on account of disability, with permission to leave the Department of Texas.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending May 19, 1894:

Ross, John W., Surgeon. Placed on the retired list. May 11, 1894.

#### Society Meetings for the Coming Week:

MONDAY, May 28th: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, May 29th: Congress of American Physicians and Surgeons (first day-Washington); American Otological Society (first day-Washington); American Neurological Association (first day-Washington); American Gynæcological Society (first day-Washington); American Dermatological Association (first day-Washington); American Pædiatric Society (first day-Washington); American Surgical Association (first day-Washington); Association of American Physicians (first day-Washington); American Orthopædic Association (first day-Washington); Association of American Anatomists (first day-Washington); American Association of Genito-urinary Surgeons (first day-Washington); American Physiological Society (first day-Washington); American Climatological Association (first day-Washington); Mt. Sinai Hospital Alumni Association, New York; Medical Societies of the Counties of Queens (annual-Mineola), Rockland (annual), and Ulster (annual), N. Y.; Boston Society of Medical Sciences (private).

Wednesday, May 30th: Congress of American Physicians and Surgeons (second day); American Otological Society (second day); American Neurological Association (second day); American Gynæcological Society (second day); American Dermatological Association (second day); American Pædiatric Society (second day); American Surgical Association (second day); American Laryngological Association (first day—Washington); American Orthopædic Association (second day); Association of American Anatomists (second day); American Association of Genito-urinary Surgeons (second day); American Physiological Society (second day); American Physiological Society (second day); American Physiological Society (second day); American Climatological Association (second day); American Physiological Society (second day); American Climatological Association (second day); American

Ophthalmological Society (first day—Washington); Auburn. N. Y., City Medical Association; Medical Society of the County of Monroe (annual—Rochester), N. Y.; Berkshire, Mass., District Medical Society (Pittsfield).

Thursday, May Stat: Congress of American Physicians and Surgeons (third day); American Otological Society (third day); American Neurological Association (third day); American Gynæcological Society (third day); American Prediatric Society (third day); American Prediatric Society (third day); American Surgical Association (third day); Association of American Physicians (third day); American Laryngological Association (second day); American Orthopædic Association (third day); Association of American Anatomists (third day); American Association of Genito-urinary Surgeons (third day); American Physiological Society (third day); American Climatological Association (third day); American Ophthalmological Society (second day); American Ophthalmological Society (second day).

FRIDAY, June 1st: Congress of American Physicians and Surgeons (fourth day); American Dermatological Association (fourth day); American Pædiatric Society (fourth day); American Surgical Association (fourth day); Association of American Physicians (fourth day); American Laryngological Association (third day); American Orthopædic Association (fourth day); American Orthopædic Association (fourth day); American Ophthalmological Society (third day); Baltimore Clinical Society.

Saturday, June 2d: Clinical Society of the New York Postgraduate Medical School and Hospital; Manhattan Medical and Surgical Society (private), New York; Miller's River, Mass., Medical Society.

#### Answers to Correspondents:

No. 425.—It probably would not have such an effect, but would simply produce coagulation. It is a violent poison.

## Wetters to the Editor.

HYOSCINE.

Chicago, May 12, 1894.

To the Editor of the New York Medical Journal:

Sir: The reading of The Extraordinary Effects of a Large Dose of Hyoseine in your issue of the 28th ultimo recalls to my mind a similar case which occurred in my practice a number of years ago, about the time that hydrobromide of hyoseine was being put on the market. I had had absolutely no clinical experience with the drug, and took the promoter's ipse dixit for what there was in it, my only knowledge of it being gained in this way.

The hydrobromide of hyoseine seemed to be indicated in the case of Mrs. E., seventy years of age, who had unfortunately been addicted to the excessive use of chloral hydrate for a period of twenty years. At times when her supply ran low, being unable to procure the chloral and having gone without it for a few hours longer than was her wont, her condition would change from one of an apparently quiet and phlegmatic temperament to one of marked mania. It was beyond our power to restrain her until the unnatural desire was appeased, and that could only be accomplished by submitting to her demands for chloral.

During one of her calm intervals she consented to permit our experimenting with a new drug and to lay aside the chloral for twenty-four hours, on the representation that what we offered was a sure remedy. Accordingly we instructed our druggist to prepare a solution to be taken  $per \circ s$ , the initial dose being  $\frac{1}{125}$  of a grain. Going directly to the patient's house from the drug store with the preparation, I administered a dose at once. Hardly had it been swallowed when there was a violent pull at the door bell, the druggist's clerk entered breathlessly, stating that an error had been made, that the dose was a poisonous one, etc., instead of being  $\frac{1}{125}$  of a grain it was  $\frac{1}{15}$  of a grain. Within a few minutes after the administration of the dose the patient complained of noises in the head, a sense of fullness, and inability to control the arms or legs or to remain sitting. The respiration was reduced one third, there was constant twitching of the muscles, the pupils were dilated, and the patient stated that she felt as if poisoned.

A bottle of whisky being at hand, I administered at once several ounces diluted with water.

In about fifteen minutes the full effects of the whisky were apparent, counteracting rapidly the hydrobromide, the muscles gradually resumed the usual tone, ringing in the ears subsided, and a feeling of drowsiness came on. At the end of an hour the patient was put to bed for the night and slept for more than six consecutive hours. This was the first sleep she had had in twenty years without the use of chloral. Of course the whisky was a factor in the immediate sleep which followed. In this case the hydrobromide proved to be the entering wedge in the successful treatment of the chloral habit, giving the old lady comparative physical and mental comfort and making the last two years of her life the best years out of more than two decades.

From the first day of administering the hydrobromide of hyoscine to the day of her death, two years later, she had not touched chloral, and was entirely free from the maniacal symptoms cited.

John McKinlook, M. D.

#### CONFUSION BETWEEN ANTISEPTIC TABLETS.

NEW YORK, May 10, 1894.

To the Editor of the New York Medical Journal :

SIR: There is the greatest danger connected with the word antiseptic when taken into consideration in its designative feature in relation to the two kinds of tablets known as the Dr. Charles Meigs-Wilson tablet and another variety of antiseptic tablet known as the Dr. Carl Seiler tablet. The formula of the latter tablet is not only known to afford a most delightful and effectual remedy for the relief of certain conditions of the mucous membranes of the nose and other cavities of the body, but the drugs therein are harmless when considered from a toxic point of view. Not so, however, with the tablet made up from the Meigs-Wilson formula. In this we have a most deadly corrosive poison to deal with, and what the consequences may be if by error the one should be substituted for the other, particularly if the directions for using the Seiler tablets should be written upon the package in which the deadly substitute has been sent to the patient's bedside, can easily be imagined. Having had a number of such occurrences in my own practice, but where, fortunately, the error was discovered in time to prevent the substitute from being used, is my chief prompter in writing this; besides, I have known it to occur in the practice of other physicians, and recently in one case with terrible

It is the duty of all manufacturers of corrosive-sublimate tablets to get into communication with each other and to come to some understanding relative to the use—abuse in this instance—of the word antiseptic in the connection under consideration and to the necessity of doing away with the word entirely, or, what would be much better still, with the manufacture of this

variety of tablet, which is a menace to the lives of those engaged in its production, and is also a constant menace to the lives of innecent beings as long as they are carried about in the reckless manner which we all, more or less, are constantly in the habit of doing. I have on many occasions got out of my bed in a terrible state of alarm, which would disappear only after I had convinced myself that I had not left a bottle of those infernal things in a household where I had been operating during the day, and where there were children who might look upon them as candy, by going to my operating bag and finding the bottle of the antiseptic tablets. Not then could I always be sure that such was not the case, for I, like many of us, have several bottles of the tablets in the operating bag at the same time.

This antiseptic is nothing more nor less, aside from being an irritant to recent wounded surfaces, than a dangerous poison; besides, it ruins the instruments with which it is allowed to come in contact, and only in exceptional cases should it be used, and these are so rare that the poison can be obtained in solution at a drug store, the amount not used to be destroyed, and a fresh supply to be provided in like manner for each additional case if there is necessity for the use of the chemical.

RICHARD H. GIBBONS, M. D.

## Reports on the Progress of Medicine.

OTOLOGY.

BY CHARLES STEDMAN BULL, M. D.

Report of Six Cases of Excision of the Tympanic Membrane and Ossicles. - Hammond (Annals of Ophth. and Otol., July, 1892) recommends the thorough cleansing of the auditory canals with hydrogen peroxide and afterward closing them with plugs of absorbent cotton, the evening before the day of operation. After excision the parts were thoroughly cleansed once daily with a hot saturated solution of boric acid, and the canal kept closed with cotton. The nose and throat were at the same time treated with alkaline spray and astringent applications. Whenever the incus was present, it was removed first, before the membrane was excised entirely. Unless this is done, the incus will be drawn upward and backward after the malleus is detached from it, in which position it becomes difficult and even impossible to remove, and it makes the danger of mastoid inflammation much greater from the position it takes at the opening of the mastoid cells into the bony canal.

The Indications for Opening the Mastoid Process in Infectious Otitis.-Orgogozo (Ann. des mal. de l'oreille et du larynx, November, 1892) thinks that in acute infectious otitis the indications for opening the mastoid may be deduced: 1. From the notion of the epidemic state, from the infectious nature of the lesion which points to the moment of intervention when suppuration is rapid. 2. From the extreme intensity of the symptoms of acute suppurative otitis, and from their persistence at an epoch when in simple cases the suppuration generally diminishes. 3. When, after a spontaneous subsidence of the symptoms, or subsequent to incision of the tympanic membrane, intense mastoid pain suddenly returns with abundant suppuration. 4. When in the absence of manifest local signs, cerebral symptoms appear-such as coma, delirium, cephalalgia, vomiting, fever, and severe pain on pressure. 5. When there is a sudden rise in the febrile curve in the course of a suppurative or non-suppurative otitis, in the period of desquamation of grave eruptive fevers complicated by otitis. 6. When there is swelling over the mastoid region with deep fluctuation.

Contribution to the Study of Intracranial Abscesses of Aural Origin.-Picqué and Février (Ann. d. mal, de l'oreille et du larynx, December, 1892) think it extremely difficult to establish an invariable rule for the course of suppuration extending from the petrous bone to the brain. The mastoid process, the posterior part of the petrous bone, its apex, or the external auditory canal, may all give rise to cerebellar abscess. Posterior lesions of the petrous bone and of the mastoid process are more likely to give rise to abscess in the cerebellum, while lesions of the superior part of the drum are more likely to cause cerebral abscess. But the germs may follow other channels, no matter where they originate. The course of these abscesses is progressive in children. The cavity increases in size, the walls become attenuated, and rupture may occur into the arachnoid or into the lateral ventricles. Cerebral abscess, no matter what its situation may be, is most frequently associated with other lesions, such as meningitis or phlebitis of the

A Scheme of Classification of the Auditory Centers in Connection with the Function of Language.-Giampietro (Ann. d. mal. de l'oreille et du larynx, March, 1893) offers the following scheme: 1. Sensory bulbar center. A destructive lesion here causes total peripheral deafness. Aphasia is an irreparable consequence when the lesion occurs before the age of two or three years. 2. Center in the optic laver. "mnemonico-volitive." The patient loses the faculty of speaking or writing in logical order. A vaso-motor lesion of this center causes transitory amnesia. 3. Center in the first temporal convolution, "ideo-phonic." A lesion here causes "ideo-phonic" amnesia or word-deafness. The patient hears the words but does not understand them. 4. Ideo-motor center in the lower border of the third frontal convolution, near the island of Reil. A lesion here causes the typical motor aphasia of Broca, and the patient loses the power of pronouncing words. 5. Ideographic center at the extremity of the second left frontal convolution. A lesion here causes agraphia and is usually associated with motor aphasia and hemiplegia.

Giampietro recognizes three function regions for the auditory nerve: 1. The external peripheral region, including the labyrinthian expansion of the auditory nerve. 2. The bulbar or sensory region or that of the reception of vibratory movements. 3. The perceptive region, in which the vibratory movements are transformed into the perception of sounds.

Deaf-mutes in Denmark. - Mygind (Arch. of Otol., xxi, 4), in a demographic sketch of deaf-mutism, finds that this condition has been on the increase in Denmark during the last twenty-five years. The male deaf-mutes are found to be both absolutely and relatively more numerous than the females. Epidemic cerebro spinal meningitis plays an important part in the present prevalence of deaf-mutism. The mortality rate is not less favorable among deaf-and-dumb children than among normal children, when the former live under good sanitary conditions. There is more deaf-mutism among the rural population than among the town population. There is no evidence of deafmutism being endemic in any place in Denmark, and the difference between the various rural districts must be principally attributed to epidemic causes. The high rate of the northern and western districts of Jutland must be attributed to recent epidemics of cerebro-spinal meningitis. The rural districts which are most heavily burdened with deaf-mutism are on the whole the least fertile and thinnest populated districts in Denmark. The majority of Danish deaf-mutes belong by birth to the agricultural population—that is, to those classes of society which are least favorably situated economically as well as socially. Only 7.1 per cent of the deaf-mutes who had left the deaf-and-dumb institutions, or who had been confined, use oral

speech exclusively as their means of communication. Deafmutes in Denmark intermarry with comparative frequency, and deaf and dumb women very frequently marry deaf and dumb men. The marriages where husband and wife were deafmutes seem to have been especially sterile. The small number of children born of deaf-mute marriages is, to some extent, owing to the fact that the average age at marriage of deaf-mutes, and their husbands or wives who were not deaf and dumb, is somewhat advanced, compared with that of the general population. It deserves notice that not a single child born in the marriages of deaf-mutes was itself deaf and dumb.

Contribution to the Surgical Treatment of Ear Diseases.—Schmiegelow (Arch. of Otol., xxi, 4) advises injections through the perforation of the drum head, in suppurative cases, with the aid of Schwartze's or Hartmann's tympanic cannulæ, in conjunction with the enlargement of the perforation by the galvano-cautery, and with the application of caustics melted upon the points of slender sounds. When necessary to perform excision of the tympanic membrane, the malleus and incus should also always be removed. In operating for carious affections of the walls of the attic, he chisels into the antrum and at the same time removes the posterior wall of the auditory canal throughout its entire length.

Observations on the Functional Examination of the Normal Ear.—Siebenmann (Arch. of. Otol., xxii, 1) summarizes the results of his work as follows: 1. The healthy ear in youth possesses a hearing distance of from twenty-five to twentysix metres for whispered numbers, and of at least fifteen metres for Politzer's acoumeter. 2. Schwabach's test with the fork A reveals considerable differences in the duration of tone perception even in perfectly normal ears. 3. In Weber's test the fork is heard louder in one ear in one eighth of the normal cases tested. 4. Rinné's test with the Bezold-Katsch fork A gives in normal cases a positive result, + forty-eight seconds being the average. 5. The upper tone limit varies little in cases where the hearing is normal. It lies between ut 9 and mi 9, as determined with König's rods. With Galton's whistle the range is within 0.6 of the minor division of the particular note which represents the limit. 6. The Bezold-Katsch fork C-1 is perceived in all cases where the hearing is normal for about sixteen seconds, the fork being struck a medium blow. 7. Aspiration of the tympanic cavity shortens the duration of perception of the fork A both by air and bone conduction. 8. Valsalvian inflation diminishes air conduction for the fork A, and usually increases bone conduction. 9. Under the influence of Valsalvian inflation the upper tone limit is usually raised; frequently also the perception of the highest scale is rendered more acute; less frequently the pitch of the middle notes of the scale is altered, Aspiration, on the other hand, either does not influence the upper tone limit at all, or lowers it somewhat. 10. Air conduction for the fork C-1 is diminished both by auto-inflation and aspiration. In isolated cases the lower tone limit is raised from C-1 to Des-1. 11. Increased tension of the annular ligament of the stapes through direct pressure upon the stapes augments bone conduction. 12. Tamponing the niches of both the labyrinthine windows does not influence the perception of high notes.

Results of the Functional Examination in Cases of Pure Catarrh of the Eustachian Tubes.—Siebenmann (Arch. of Otol., xxii, 1) gives the results of his work as follows: I. The test of bilateral tubal catarrh exhibits the following functional changes: 1. Diminution of air conduction. 2. Increase of bone conduction. 3. Localization of the tuning fork placed on the vertex upon the more affected side. 4. Shortening of Rinné's test, or its reversal to negative. 5. Elevation of the lower tone limit. 6. Reduction of the upper tone limit.

II. The first inflation does not notably influence either the increased bone conduction or the reduction of the upper tone limit; on the other hand, it improves in no small degree the diminished air conduction and the narrowing of the lower tone limit, without restoring them to their normal standard. After the air douche the hearing is increased out of all proportion to the increased bone conduction.

A Case of Unilateral Total Absence of the Labyrinth caused by Scarlatineus Otitis Intima.—Mygind (Arch. of Otol., xx, 1) reports a case of this nature, in which the point of greatest pathological interest is the total absence of the labyrinth on the left side. The absence of the internal ear, which was so complete that no traces of the normal labyrinth cavities were to be found, seems to be a very rare pathological condition. It proves that the bone tissue, which is formed as the product of a post-feetal otitis intima, is able to fill up the normal cavities of the labyrinth so thoroughly, and assume the appearance of the surrounding bone so completely, that every trace of the outlines of the original cavities disappears entirely.

Histology of Two Petrous Bones of a Girl completely Deaf from Scarlet Fever; Died of Purulent Meningitis.— Moos (Arch. of Otol., xxii, 1) considers the following points of interest as the result of the terminal affection: 1. The recent purulent inflammation in the niches of both fenestræ. It is remarkable that the greatest portion of the mucous membrane of the labyrinth wall, transformed into epidermis, was not only free from any recent inflammation, but even without cell elements and any vessels to speak of. The epidermoidal integument certainly offered a great resistance to the invasion of micro-organisms from without. 2. The recent necrosis of the facial canal and the niche of the fenestra ovalis. 3. The bilateral necrosis of the cochlear capsule and the partial destruction of the osseous tissue in the scala tympani of the first whorl of the right cochlea. 4. The more or less extensive inflammation of both vestibular apparatus. 5. The destruction of the auditory nerves and a portion of the facial nerves by suppuration and hæmorrhage. The almost symmetrical necrosis of both cochleæ from the porus acusticus internus to the labyrinth wall shows the possibility of a secondary bilateral otitis media starting from the labyrinth.

Functional Deafness and Destruction of the Membrana Tympani caused by an Electric Shock while using a Telephone.—Robinson (Annals of Ophth. and Otol., January, 1893) reports a case of this nature in a man, aged forty-five years, who had the receiver of a telephone to his ear when a flash of lightning appeared, and he fell unconscious to the floor and remained so four minutes. On regaining consciousness he had very severe pain in the left ear and left face, left breast, arm, and leg. The intensity of the pain diminished in four hours. The senses of taste and smell were impaired. Field and acuity of vision normal. The left membrana tympani was almost totally destroyed, the edges of the remainder being ragged, uneven, and congested. There was no discharge, but the mucous membrane of the middle ear was swollen. Hearing for the watch = 0. A C tuning fork was heard half an inch by aerial and less well by bone conduction. Two months later he began to regain his hearing, and the membrana tympani was being rapidly restored. Thirteen months after the accident the condition of the ear was almost entirely normal.

Report of Six Cases of Excision of the Tympanic Membrane and Ossicles.—Hammond (Annals of Ophth. and Otol., July, 1892) reports six cases of this nature, in some of which the diseased process was a sclerosing one, and in others a suppurative one. In the sclerotic cases the canals were thoroughly cleansed with hydrogen peroxide the evening before operating, and then closed with plugs of absorbent cotton. By this means

the congestion which always follows the cleansing of the canal and membrane was avoided. After excision the parts were thoroughly cleansed once daily with a hot saturated solution of boric acid, and the canals kept closed with cotton. The nose and throat were at the same time treated with alkaline spray and astringent applications. In the suppurating cases the parts were cleansed with a hot saturated solution of boric acid just before operation. In all the cases where the incus was present, it was removed first by making an incision round the shank, when it was easily disarticulated by passing the looped curette between the articulation with the malleus, at the same time drawing it forward. Unless the incus is first removed, it will be drawn upward and backward after the malleus is detached from it, in which position it becomes difficult and even impossible to remove, and makes the danger of mastoid inflammation much greater from the position it takes at the opening of the mastoid cells into the bony canal.

The Bougie as a Means of Treatment in Diseases of the Middle Ear.—Harris (Annals of Ophth. and Otol., July, 1892) thinks that physicians have become timorous in their employment of the bougie, partly owing to the unsatisfactory material of which it is made, and partly to lack of knowledge as to its method of introduction. A suitable material is celluloid, introduced by Urbantschitsch. The bougies should be six to eight inches long, bulbed at each end, and of six sizes, graded according to Charrière's scales. These bougies are very durable, and having bulbous heads at both ends are really two bougies in one. In introducing them, care should be taken to avoid violence, and strict antiseptic precautions should be observed. A common source of error is found in the lodgment of the catheter in the fossa of Rosenmüller instead of in the pharyngeal opening of the tube. If the mouth of the tube is large, an indistinct sound will be perceived with the diagnostic tube which can easily deceive one into thinking the instrument is in place; the bulb of the bougie, however, will at once encounter a firm obstruction, or, if any force is exerted, the bougie may progress, but will be bent.

An Aural Reflex.—Maloney (Annals of Ophth. and Otol., October, 1892) has noticed on a number of occasions in different pianists forced efforts at expiration. In one instance, by placing three or four flat piedgets of cotton in the auditory canals with a space between each, so that a low voice could not be heard, and the performer being requested to play by signs, there was not the slightest sign of forced expiration. This test afforded proof that it was not due to tactile sense, but was a true auditory antecedent effect. Maloney thinks that the phenomenon is due to irritation of the tensor tympani nerve, and is reflected to the vagus through the otic ganglion, thence to the non-striated muscle of the entire bronchial system, which offers resistance to increased pressure within the air-passages as in forced expiration.

The Ear of Man and the Organ of Corti.—Maloney (Annals of Ophth. and Otol., April, 1893) believes that increase and decrease of resistance or pressure is the most potent factor in audition, in contradistinction to mass vibration through or individual excursions upon the part of the ossicula. The increased or diminished pressure upon the perilymph caused by corresponding pressure of the foot-plate of the stapes through the oval window finds its compensation in the bulging inward instead of outward of the round window. The telephone performs the function of the human ear, and is an analogue because its function is a scientific truth. The nerves in the internal ear, like nerve-fibers elsewhere in the body, are entirely surrounded and incapable of vibrating as piano strings. While the ear has strings representing seven octaves and a third, it is impossible to get a semblance of reproduction of either composite or other

tones from impact of sound waves on them; each string will only respond to its fundamental.

Ottice Brain Disease; its Varieties, Diagnosis, Prognosis, and Treatment.—Knapp (Arch. of Otol., xxii, 2) considers it difficult to recognize when meningeal irritation passes over into true meningeal inflammation. As soon as in the course of otitis media, with its manifold symptoms, the headache becomes persistent, is followed by attacks of nausea and vomiting, dizziness, drowsiness, delirium, or stupor, at first acceleration and later retardation of pulse and rise of temperature, dry tongue, thirst, and constipation, we may be sure that meningitis has begun or is fully developed. The lethal issue is commonly preceded by spasms in the extremities and count.

The Hearing Power in Deaf-mutes; being the Results of the Examination of One Hundred and Seventy-five Deafmute Children,-Love (Arch. of Otol., xx, 2) draws the following conclusions from his observations: 1. Total deafness is very rare among deaf-mutes. For aerial sounds it is not greater than seven or eight per cent., and for bone-conduction sounds even less. 2. Hearing for speech is rather common. It exists to a utilizable extent in twenty-five or twenty-seven per cent. of deaf-mutes, and from ten to fifteen per-cent. are only semimute. Under the finger system of teaching these semi-mutes become rapidly deafer, and soon totally dumb. The oral system may do something to prevent this, but it can only be properly dealt with by the acoustic method. 3. Cranial conduction exists in almost all cases, and a large vibrating tuning fork is almost always heard in this way. It is also beard in the majority of cases by aerial conduction. In only a small number of cases can a watch or Politzer's acoumeter be heard.

The Propagation of Affections of the Tympanum through the Carotid Canal into the Cerebral Cavity.-Körner (Arch. of Otol., xxii, 2) states that even in simple suppurative inflammation of the mucous membrane of the middle ear purulent exudation has been found in the carotid canal as well as purulent infiltration of the adventitia of the carotid artery. If the osseous wall of the canal is destroyed, osseous pus, of course, reaches the canal and surrounds the lymph vessels and venous plexus. When these lymph vessels are surrounded by pus they may become inflamed and filled with thrombi. The venous plexus connected with the cavernous sinus may also be affected by the presence of pus in the carotid canal, and this may be propagated into the lateral sinus. When pus is retained in the tympanum with pyæmic symptoms, simultaneous paralysis of the abducens and bilateral papillitis have been observed. Erosion of the carotid wall and fatal hæmorrhages have also been reported. Tuberculosis may also be propagated from the tympanum along the vessels of the pia. Cerebral embolism has also been known to occur in consequence of thrombosis of the carotid artery in purulent otitis media and caries of the temporal bone.

A Case of Otitis Media Purulenta with Caries of the Mastoid Process due to Caries of the Second Molar Tooth.
—Schwartz (Arch. of Otol., xxii, 2) reports a case of this kind in a young man aged twenty-one years. The caries was transmitted to the upper jaw, whence the fistula occurred in the hard palate, and this was readily closed after the removal of the tooth. Thence the poison affected the periostum and simultaneously the mucous membrane on the left nasal floor. The periostitis extended from this region through the Eustachian tube into the tympanum and osseous portion of the external meatus, and formed a circumscribed and hemispherical infiltration, corresponding with the tympanic opening of the Eustachian tube, which at first resembled a genuine exostosis.

The Clinical Signs of Affections of the Auditory Nerve.

—Gradenigo (Arch., of Otol., xxii, 2) notes the following clini-

cal characteristics: 1. Diminution of the acuteness of hearing demonstrated by examination with tuning forks, especially with forks of middle register. Acuteness of hearing for high tones diminishes the earliest. The functional defect for middle tones increases in some cases to a complete disappearance of perception for some of these tones (for example, c1). 2. Excessive functional exhaustibility to a marked degree. It is often so considerable that the results of the examinations by the different methods become so essentially modified that it is impossible to form an accurate conclusion as to the amount of hearing power present. The best way to study this functional exhaustibility is by means of an instrument modeled on a telephone audiometer. First determine the least intensity of tone that can be perceived; then expose the ear for a minute or two to the greatest intensity of the same tone which can be obtained from the instrument; then reduce the tone quickly to the minimum intensity heard in the beginning. The perception for this low intensity either ceases for several seconds or is entirely lost, After establishing the minimum intensity that can be perceived the ear is then exposed to the action of that tone. If the functional exhaustibility is considerable, the patient, after a few seconds, ceases to perceive it. In order to renew the perception it is necessary that the intensity of the tone be progressively increased from time to time. In some isolated cases it is possible to recognize that the functional exhaustibility precedes a temporary increase of the power of hearing.

Removal of the Stapes,-Blake (Arch. of Otol., xxii, 2) here describes the modification of the first stage of the operation, that of incision of the membrana tympani, in reference both to the manner of employing the local anæsthetic and of making the cut. The strength of the cocaine solution is reduced to two per cent. The introduction of the solution through the Eustachian catheter is replaced by simple instillation of a few drops of a two-per-cent. solution in the nostril of the side to be operated upon, the head being inclined backward toward the corresponding side, or by a preliminary incision in the membrana tympani, and the solution then dropped through the cut. The incision procedure is divided into two parts, the first consisting in the opening already described, beginning at the round window and following the periphery to the short process of the malleus; the second beginning behind and half-way down the length of the manubrium, and being carried upward to meet the termination of the first cut, the intratympanic steps of the operation remaining the same as previously described. One of the notable points in some of these cases is the evident improvement in hearing by bone conduction as the result of the removal of a fixation obstacle, which impaired the intralabyrinthme sound transmission in accordance with a law governing the propagation of sonorous vibrations in fluid in inclosed spaces; and the occurrence of the vertigo coincidently with the outflow of fluid, presumably labyrinthine, would permit at least the inference that the vertigo was the result of a change in a fixation condition to which the parts had become accustomed, and that the release from supporting pressure consequent on the outflow of the labyrinthine fluid was accompanied by a congestion in the semicircular canals giving rise to those symptoms of general vertigo which the patient experienced.

Opening the Drum Cavity by Kuester's Method.—Maurel (Rev. de largng, et d'atol., March 1, 1893) describes Kuster's operation of removing partially or wholly the posterior-superior wall of the bony auditory canal, and then the external wall of the attic. He makes an incision behind the line of insertion of the concha. The soft parts are separated as far as the periosteum, which is then dissected free and pushed backward. The membranous or cartilaginous portion of the external auditory canal is then detached from its posterior and superior insertion, and is

turned forward and downward with the concha. The mastoid apophysis and the bony margin of the postero-superior wall of the canal being exposed, search must be made for fistulous orifices or carious portions, and, if found, they must be enlarged and their contents, with all carious bone, must be removed. If the lesions are limited to the external part of the canal, the parts must be carefully curetted. The mastoid antrum is then opened by removing entirely its posterior, external, and inferior walls, and the tympanic cavity is thus directly opened.

The Microbes of the Ear.—Martha (Ann. des mal. de l'oreille et du larynx, July, 1893) has examined the secretions from the ears of fifty patients, and found in twenty-seven cases the staphylococcus, in eighteen cases the streptococcus, in two cases the Bacillus pyocyanicus, and in many cases the tetragonus and versicolor. In no case did he discover the pneumococcus. Many of these microbes were found adherent to the aural specula, even those which had been apparently thoroughly cleansed, but which had not been passed through and exposed to the flame of a lamp. Hence he emphasizes the necessity of complete antisepsis of the instruments and medicaments employed in the examination and treatment of cases.

Deafness in Retarded Tertiary Syphilis, Acquired or Hereditary .- Delie (Ann. des mal. de l'oreille et du larynx, August, 1893) gives the pathognomonic symptoms of aural disease due to retarded syphilis as follows: 1. Sudden appearance of vertigo with loss of equilibrium. 2. Tinnitus and vomiting. 3. Complete deafness, generally bilateral. All the symptoms gradually improve and finally disappear, except the deafness, which remains absolute and incurable. If the patient has previously had some affection of the middle ear, the deafness becomes suddenly aggravated, and in a few hours or days becomes absolute; the tuning fork can no longer be heard to vibrate when placed in contact with the bones of the skull. Usually this sudden and absolute deafness occurs in the children of syphilitic parents without the slightest premonitory symptom; but these children will be found to have had changes in the incisor teeth and usually some form of eye trouble. In acquired syphilis the deafness may appear toward the end of the second period (one or two years after the chancre), or in the course of the third period (after the fourth year). Generally, however, when the hearing is intact in a syphilitic subject, sudden deafness with Ménière's symptoms appears late in the tertiary period, ten to fifteen years after infection. In hereditary syphilis the critical period is at the beginning of puberty. Girls are more frequently attacked by sudden deafness than boys.

Three Cases of Unintentional Opening of the Lateral Sinus.—Sheppard (Arch. of Otol., xxii, 3) reports three cases. The interesting features of the first case were: 1. The relatively slight symptoms preceding and indicating operation, compared with the enormous destruction of tissue within the mastoid, involving even a large portion of the inner wall, as well as the absence of any serious consequences from the double puncture into the lateral sinus and into the brain cavity. 2. The severe chill on the fourth day after operation, preceded by no unpleasant symptoms and followed by an uninterrupted recovery. 3. The attacks of vertigo with loss of consciousness, irregular respiration, and slow pulse during the month following the final healing. In the absence of a bony wall between the mastoid and cranial cavities, could the cicatricial contraction have caused sufficiently increased intracranial tension to account for the symptoms?

In the second case the prominent features were: 1. The manner in which the sinus was apparently opened—that is, the flow of blood came after removing a pledget of cotton used for drying out the cavity. It seems probable that with the curette a piece of necrotic bone wounded the sinus wall, but was not

sufficiently displaced to allow of hamorrhage until caught in the cotton and removed. 2. The entire absence of disturbing symptoms, with the relatively short time required for entire healing of the wound.

In the third case the mastoid suppuration occurred on the side upon which there was apparently a lesser grade of inflammation in the tympanic cavity. The sinus here was probably opened by a splinter from the inner plate caused by using the curette, the splinter penetrating the sinus wall.

Short Description of the Temporal Bones of Deaf-mutes belonging to the Pathological Museum of the Copenhagen University.—Mygind (Arch. of Otol., xxii, 3) found in this large collection of preparations that the osseous parts of the auditory organs in more than one half of the cases were not the seat of any abnormity that could be demonstrated. As far as the nature of the abnormities was concerned, the morbid changes found in the deaf-born were only exceptionally the expression of malformations or deformities caused by arrest of development. In the majority of cases they were the result of fætal inflammatory processes, which caused a partial destruction of the internal osseous structure of the labyrinth and in many cases the consequent formation of osseous tissue. The comparatarus of the cochlea, thus causing a large cavity in the top of the organ without the normal osseous contents, while the lower parts of the cochlea were completely or almost completely preserved, was probably the result of a destructive feetal inflammatory process. The examination of the temporal bones of deaf-mutes whose deafness had been acquired after birth proved that the pathological changes generally consisted in the deposit of osseous matter in the normal cavities of the labyrinth. The osseous mass closing the cavity was often not to be distinguished

from the surrounding bone of the pars petrosa either in color, drawn under the artery, when it is tied. I have used the for or consistence, while in some it was clearly distinguishable, owing partly to its greater whiteness, partly to its firmer, more ivory-like consistence.

## New Inbentions, etc.

NEW INSTRUMENTS.

By J. S. Wight, M. D.,

PROFESSOR OF OPERATIVE AND CLINICAL SURGERY AT THE LONG ISLAND COLLEGE HOSPITAL, BROOKLYN, N. Y

I. The Hook-eye Needle.—This needle is split at the eye end: one piece is bent into a book to make the eye; the other piece projects beyond the hook to catch the thread and guide it into

the hook-eye. The continuity of the thread is placed on the projection and carried into the hook-eye in an instant. The needle is pushed through the flap, for instance, from within

the other flap, also from within outward. The shaft of the needle is a cylinder, but the point is flattened, and has a sharp beveled point resembling that of the Hagedorn needle. In Fig. 1, a represents a straight needle, having the point made quadrangular. This point penetrates more readily than a "round one," and it does not cut so much as a "triangular one"; b represents a short, strong needle with a curved point, intended for gynæcological operations; c represents a large curved needle for the use of the general surgeon. I have used this needle in a number of operations-amputations, laparotomies, wounds, etc. It facilitates work and saves time.

II. The Forceps Aneurysm Needle .- This instrument is a modification of my artery forceps. The parts of this instrument are shown in Fig. 2: a is a needle point having an eye; b is simply an eye point; c is a mouse-tooth point. The entire instrument is represented as carrying a ligature. The Tiemann catch for the forceps is an essential part of the mechanism. This catch makes the fulcrum. Side handles are so arranged that they can be compressed by the thumb and fingers of the surgeon, opening the ends of the jaws of the forceps. The curved jaws of the forceps are carried under the artery in the usual way, the thumb-pieces are compressed, and the ligature tively frequent abnormity consisting in destruction of the upper is put into the eye, or between the ends of the jaws, and then

ceps aneurysm needle in a case of gunshot wound of the common carotid and the internal jugular; in ligating the common carotid for arrest of hæmorrhage in cancer of the neck; in case of large varicose internal saphenous vein; in removal of omentum in strangulated hernia; in excision of the testicle. This aneurysm needle can be used as hæmostatic forceps. These instruments are made by George Tiemann & Co., 107 Park Row, New York.

## Miscellany.

Rigor Mortis.—At a recent meeting of the Paris Académie des sciences, a report of which is published in the Union médicale for April 28th, a note on this subject by M. J. Tissot was presented by M. Chauveau. The author remarks that two opposite opinions are held by physiologists as to the nature of cadaveric rigidity. Some, such as Brücke and Kühne, maintain that it is due to a chemical phenomenon, coagulation of the myosin. Others, such as Nysten and Brown-Séquard, look upon it as a final muscular contraction, that is to say, a physiological occurrence. The only facts, M. Tissot says, that warrant the latter hypothesis are the analogies of cadaveric rigidity with muscular contraction and the observations published by Brown-Séquard. None of the essential vital manifestations have yet been observed in the rigid muscles. Experiments made by the author himself have shown the following results: 1. Very often the rigid muscles remain capable of electrical excitation outward, and is then instantly rethreaded and pushed through during a variable period in the early portion of the rigidity and

even when it is completely established. This persistence of excitability is almost constant whenever the rigidity has come on rapidly. 2. The rigid muscles that have lost their electrical excitability may preserve their mechanical excitability for a long time. 3. Rigid muscles that have lost both electrical and mechanical excitability still respond to chemical stimuli. Contrary to what most physiologists have said, the sensitiveness of the muscles to chemical agents, such as chloroform, ammonia, etc., persists much longer than their mechanical excitability, and is always the last to be lost. 4. While the electrical excitability goes on decreasing, the excitability in response to certain agents increases in inverse ratio, and attains its maximum when the electrical excitability is disappearing and at the moment when the muscles are about to enter upon the state of rigidity. For other chemical agents the excitability decreases regularly without having attained the maximum. It is futile to seek to ascertain from the action of one or two agents, as many physiologists have done, the behavior of muscles toward chemical excitants in general, and it may be said that muscle behaves differently with each of them. 5. Tetanized and fatigued muscles present the same exaggerated sensibility to like chemical excitants as rigid muscles do. The same is observed in muscles the vessels of which have been tied for a certain time and in muscles subjected to causes of impairment, such as contact with the air, heat, drying, etc. 6. The contraction produced in a rigid muscle by an excitant, even by a small amount of vapor, such as that of chloroform or ammonia, is accompanied by a current in the muscle. It is accompanied also by the disengagement of heat, as in normal muscular contraction. 7. Rigid muscles hung up in the air absorb oxygen and give off carbonic acid. 8. In two cases the author has been able to cause the appearance of rigidity in the frog's gastrocnemius by a single intense electrical excitation a little before the instant when the muscle loses its electrical excitability; he has not yet been able to ascertain the conditions under which this phenomenon is produced.

Topical Applications of Guaiacol in Diseases of the Throat .- The New York correspondent of the Journal des praticiens summarizes the experience of a number of Chicago physicians in the use of guaiacol applied to the mucous membrane of the throat. Dr. Ingals is cited as thinking highly of these applications in acute affections of the throat. Dr. Cotton is said to have observed an immediate and considerable amelioration in ninety-four per cent. of the patients so treated. Dr. Rhodes is said to entertain an equally high opinion of the remedy. He has even employed it successfully in erysipelas of the face. Dr. Corwin has reported fifteen cases of amygdalitis treated successfully with applications of guaiacol. In every instance amelioration followed the first application of the remedy. Dr. Raymond has employed pure guaiacol. A fifty-per-cent. solution in oil of sweet almonds may also be applied in the form of a spray, but this procedure is said to be less effective than painting with pure guaiacol. Sometimes the application is disagreeable and is accompanied with rather a brisk sensation of burning; but this is of short duration, commonly not more than from a minute to five minutes. Occasionally, however, the disagreeable sensations are prolonged for several hours. It may be said that painting with guaiacol is no more painful than the application of a good many remedies which are in ordinary use, and it possesses the advantage over them of being curative and very often abortive. It might be thought, the correspondent continues, that the previous application of a ten-per-cent. solution of cocaine would mitigate the sensation of burning caused by the guaiacol; on the contrary, this procedure seems to render the burning more painful. In making the applications a tampon of absorbent cotton saturated with pure guaiacol is swept over the whole surface of the tonsil, great care being taken that none of it drops into the larynx. In every case it has been observed that the temperature fell to the normal point or within a degree of it. Often two applications are sufficient to abort the disease. In patients who had been unable to swallow without great pain guaiacol has often made swallowing easy.

Acute Poisoning with Therapeutic Doses of Creosote .-In the Centralblatt für innere Medicin for May 5th Dr. Zawadzski reports a case in which a woman forty-two years old was ordered creosote in doses of six drops three times a day, in milk. After she had taken three doses symptoms of poisoning showed themselves, including those of high irritation of the gastro-intestinal canal, anæsthesia, and partial paralysis of the soft palate and of the vocal bands, persistent burning in the mucous membrane of the mouth and pharynx, albuminuria, signs of weakness of the heart, and especially the exhalation of the odor of creosote from the mouth. Death took place in the course of four days, and the author thinks it was owing to an idiosyncrasy that made the patient abnormally sensitive to creosote. He expresses the opinion that we should avoid using creosote pure or in strong solutions, and especially that creosote should not be ordered to be taken in milk, since it is insoluble in milk and, when so prescribed, acts as if it were undiluted. Moreover, he thinks that not more than one or two drops at a dose should be ordered to begin with, and that this dose should be increased gradually.

Diffuse Hypertrophy of the Breasts. - The Deutsche Medizinal-Zeitung for May 3d gives an abstract from a Hungarian journal of a case of this sort related by Dr. Herczel. The patient, twenty-nine years old, was in the fourth month of pregnancy. The hypertrophy had existed for six weeks. It was so great that when she sat down the breasts rested on the thighs. The consistence of the organs was that of a breast during lactation, without any hard or fluctuating parts. An additional feature of interest in this case was that there was an accessory breast, half as large again as one's fist, situated in the axilla. The breasts were not painful on pressure, but there was pain in the left breast when the patient lay down. The author remarks that it is well known that hypertrophy of the breasts is apt to show itself at puberty or during pregnancy, and he says that it is very important to distinguish between the two cases, because in the first amputation may become necessary, whereas in the second the breasts always recover their natural size after delivery.

The Paris Faculty of Medicine.—The Progrès médical announces that M. Germain Sée, professor of clinical medicine, has been retired at his own request on account of the state of his health, and that M. Chantemesse, agrégé, has been chosen to take his place until the 30th of October. The Wiener medicinische Wochenschrift states that Dr. Malussez has been nominated to succeed Professor Charcot in the chair of pathological anatomy.

The University of Vienna.—The Wiener medicinische Wochenschrift states that Dr. Joseph Gruber and Dr. Politzer, heretofore extraordinary professors of otology, and also Dr. Karl Stoerke, extraordinary professor of laryngology, have been made ordinary professors.

The Treatment of Epistaxis.—The May number of the Glasgow Medical Journal contains a paper entitled Notes and Observations on Certain Forms of Epistaxis, by Dr. Robert Fullerton, read at a meeting of the Glasgow Southern Medical So-

ciety. In regard to the treatment of bleeding from the nose, the author thinks that, in young and plethoric persons, also where there is any likelihood of an apoplectic seizure, some hesitation should be felt as to stopping the bleeding. A careful examination of the nasal cavities should be made in every case, if possible, especially if the hemorrhage has been profuse or recurrent. The causes may be local or constitutional, and in the treatment constitutional influences should not be lost sight of. It is important to remember that in most cases the bleeding point is situated anteriorly, so that the flow may easily be checked by plugging from the front. In most cases the hæmorrhage may be controlled temporarily by the patient's grasping the anterior cartilaginous portion of the nose firmly. It should then be plugged from the front, preferably with a long strip of iodoform gauze, which is to be pushed carefully upward, backward, and downward with a probe or a sinus forceps, layer upon layer, until the cavity is thoroughly packed. If this is done thoroughly, the cases are very few in which anything further is required for the time being. The advantages of using the iodoform-gauze strip are that the parts remain aseptic for a considerable time, and that the continuous character of the packing permits of its easy removal. The plug should not remain in for more than forty-eight hours, and in withdrawing it the utmost care should be taken not to displace any clot that may have formed. As a rule, on removing the plug, the surface of the nasal cavity will be found fairly free from blood; but any blood that obscures the parts can be removed by spraying, or wiped off with cotton wool on a probe. After this has been done, an effort should be made to discover the bleeding point with the aid of a good light and with the nostril well dilated. Particular attention should be directed to a careful examination of the sæptum with a probe, to see if bleeding can anywhere be elicited. Any clot or suspicious mark should be examined in the same way, and temporary pressure applied to it if necessary as a preliminary to effecting a radical cure. For this purpose the author has used nitrate of silver and chromic acid; but, while each has acted satisfactorily for a time, neither has been permanent in its effect. On the other hand, the galvanic cautery has acted perfectly in every case. Before using this, it is desirable to apply a five-per-cent. or a ten-per-cent. solution of cocaine to the spot to be touched. The cautery should be passed slowly down through the soft tissues at a red heat, and should be kept glowing until it is again clear of the parts. If this last point is not attended to, the tissue is apt to adhere to the cautery, so that on detachment of the clot bleeding takes place anew. If a galvanic cautery is not at hand, the end of a probe heated in a spirit lamp may be used, and the author thinks it would be more efficient than either chromic acid or nitrate of silver. In plugging, cotton wool may be used, with or without the addition of a styptic. Perchloride of iron is an effective but most unpleasant application. A four-per-cent, solution of antipyrine is said to act well, but the author thinks that styptics are unnecessary, provided pressure by means of plugging is carried out carefully. Where the hæmorrhage is moderate, a fiveper-cent. solution of cocaine, sprayed or sniffed, acts well and quickly. Where there is only slight capillary oozing, a preparation of hamamelis may be applied several times a day in the form of spraying. Under such circumstances also an ointment of menthol and vaseline, which the patient can sniff up, generally acts satisfactorily.

Fragmentary Bone-grafting.—In the Province médicale for April 28th there is an article on this subject by M. Vallas in which he remarks that satisfactory results from bone-grafting have not yet been realized, and the reason, he thinks, lies in the ply the loss of bony substance, grafting may serve as a useful adjuvant to the physiological process of ossification; it can not be the principal factor or the sole agent. The observations which have been published up to the present time go to support this theory. Dr. Patterson, of Glasgow (Lancet, 1878), in treating a case of pseudarthrosis of the forearm, employed massive and heteroplastic bone-grafting. He placed a piece of dog's bone between the two fragments, and this seemed to become grafted and united at first, but twelve months afterward it was cast off in the form of a bony fragment of about half the size of the original graft. M. Ollier has observed the case of a young girl on whom he had grafted an osteo-periosteal strip a hundred and fourteen millimetres long in the tibia taken from the tibia of the opposite side. The wound healed without suppuration: but at the end of four months the greater part of the graft had been cast off. The edges were worn and jagged, and the periosteum alone had become grafted. Thus the massive graft had not united. The new bone which had been introduced into the organism might have been tolerated as an aseptic foreign body, but it would not succeed in setting up the nutritive interchange which constitutes the life that is characteristic of true grafting.

Fragmentary grafting has shown more satisfactory results. M. Poncet, of Lyons, has observed a case of total diaphyseal necrosis of the tibia. He sowed small fragments of a young goat's bone in the periosteal sheath. Some of these fragments were cast off, but others remained and were united in the bony masses of new production. It was observed that, in this case, the grafting had served only as an auxiliary procedure, for the periosteal sheath of the young patient, who had been attacked with acute osteomyelitis, was in full vigor and in a fair way to reproduce the old bone. The grafting had only hastened the work of normal ossification, not replaced it. In another case observed by Dr. Macewen (Rev. de chirurgie, 1882), the patient, a child three years old, had had acute diaphyseal necrosis of the humerus. The operation was not performed for a year, in order to cure the pseudarthrosis which had resulted from the absence of regeneration. Three times Dr. Macewen grafted fragments of bone in the fibrous cord which represented the periosteal sheath. He was fortunate enough to re-establish the continuity of the humerus. In summing up this case, in his Traité des résections, M. Ollier concludes from the examination of these facts and from his experiments on animals that grafting acts as a temporary aid in renewing the osteogenetic properties of a tissue capable of physiological ossification. Fragmentary bone-grafting is of assistance in hastening tardy consolidation or in filling bony cavities of which the spontaneous obliteration is slow in taking place. In the latter case especially, it is preferable to the employment of catgut or other foreign bodies which have been used for this purpose.

Symptomatic Treatment.-In an address on Influenza, introductory to a discussion of the subject in the Harveian Society of London (Lancet, April 28th), Dr. Samuel West said:

"The treatment of symptoms is often spoken of with some contempt-not, I think, by clinical physicians, who are not prepared to discard remedies because they can not explain their action. It is sufficient for them that experience proves the value of the drugs they use. It is true that we have so far no remedies which will kill disease germs in the body, and therefore directly cure any germ disease; but the germs produce poisons, and these, by their action on the body, in all probability cause the symptoms of the disease. These poisons we may be able to neutralize or destroy, if we can not kill the germ. What the poisonous substances produced are we do not know, fact that too much has been expected from it. In order to sup- and for antidotes to them we are, and have long been, groping, in great darkness, it is true; yet I think it not unlikely, when these poisons are isolated and investigated outside the body, that among the old and once-trusted remedies, which empiricism has discovered and fashion discarded, will be found some of the true antidotes we want, and thus the symptomatic treatment of disease, now regarded as so unscientific and irrational, be discovered to rest upon a truly scientific foundation."

The Radical Cure of Epithelial Cancer of the Skin,—According to the Microrali midlical, Dr. Gavino related at the recent International Medical Congress, held at Rome, a method of treatment by which he had succeeded in curing epithelial cancer of the skin. He applies a preparation consisting of ten parts of fuming nitric acid and four parts of bichloride of mercury, brought to the consistence of syrup by the addition of bibulous paper. This is applied on a bit of cotton. At the end of ten or twelve days the cauterization is repeated; this is enough to cause the largest tumor to drop off. Perfect cicatrization is rapid. The author states that up to the present time he has cured all his patients, but the account does not say how many of them there have been.

Lichen and its Varieties.—In the April number of the British Journal of Dermatology there is a paper that was read in the Section in Dermatology of the Eleventh International Medical Congress by Mr. Malcolm Morris. Mr. Morris summarizes his paper substantially as follows: Lichen is not a disease, but a typical form of lesion. The name lichen should be reserved for what Erasmus Wilson described as lichen planus, which is the same as Hebra's lichen rubra. Kaposi's lichen rubra acuminatus is the same thing as the pityriasis rubra pilaris of Devergie and Besnier. Lichen planus is probably due to a variety of factors, but we are still almost wholly in the dark as to its pathogenesis.

An Antiseptic and Anæsthetic Liquid.—At a recent meeting of the Société des sciences médicales de Lyon, reported in the Mercredi médical for May 2d, M. Mayet gave the formula of an antiseptic and anæsthetic liquid to be employed on tampons in various affections of the uterus and in dressing small wounds. The formula called for two hundred parts of sterilized vaseline, two parts of cocaine, and eight parts of oleic acid. It was stated that, inasmuch as there was danger of the absorption of the cocaine, this dressing should not be applied to extensive wounds.

Carbolic Acid and Chloroform in the Treatment of Typhoid Fever .- In the British Medical Journal for April 28th Surgeon-lieutenant-colonel Quill, of the medical staff of the British army, recommends a mixture of thirty-six minims of Calvert's pure carbolic acid, two fluidrachms of spirit of chloroform, three fluidrachms of compound tincture of cardamom, two fluidounces of syrup of hemidesmus, and enough chloroform water to make twelve fluidounces. A fluidounce of this mixture, with an equal quantity of ice water, is to be taken every two hours. The author says it is important to continue the use of the mixture in from three to five doses daily for at least a week after the temperature has fallen to the normal point; this renders the patient less liable to a relapse. Surgeon Quill states that during the past year he has treated with this mixture all the cases of typhoid fever that have come under his care, and in every case perfect recovery has followed without the occurrence of any symptom calculated to cause anxiety: but he does not state how many he has had. He has observed the following effects of the use of carbolic acid and chloroform: 1. A reduction of the average duration of the fever. 2. A continuous depression of the febrile temperature. 3. Early cleansing of the tongue, which was rarely observed to be dry and then only for the time being. 4. An almost complete deodorization of the stools. 5. Entire absence of abdominal distention. 6. Checking of the tendency to diarrhœa. 7. Preservation of the patient's intellectual clearness, with no tendency to stupor or delirium. 8. The non-occurrence of any kind of secondary complication. 9. Rarity of relapses and their brief duration when they occurred. 10. The invariably satisfactory assimilation of food. 11. Rapidity of convalescence.

Symphysiotomy. - In the Gazette Lebdom idaire de médecine et de chirurgie for May 5th there is an exhaustive review of this procedure by M. Pinard, of the Paris Faculty of Medicine. He closes with the following conclusions: 1. Aseptic symphysiotomy is not a dangerous operation. 2. To be of service it should be complete, and the amount of separation of the two public bones should be proportionate to the degree of contraction of the pelvis. 3. The operation should not be attempted unless it has been calculated that a separation of seven centimetres will allow of the passage of the full-grown feetal head. 4. Since separation of the pubic bones to a greater distance than seven centimetres may result in injury of the soft parts, it should be interdicted. 5. When a separation of seven centimetres does not suffice for the passage of the feetal head, Porro's operation should be performed. 6. In cases of oblique oval pelvis, with synostosis of one of the sacro-iliac synchondroses, if the contraction does not permit of spontaneous delivery-and this can be ascertained only after labor has set inwe should perform Farabeuf's operation (separation at the ischio-pubic articulation), and for this we should be prepared at the outset. 7. In case labor is impeded by ankylosis of the coccyx, coccygotomy should be practiced.

The Relations of the Axillary Artery.-In the May number of the Edinburgh Medical Journal Mr. J. Ryland Whitaker criticises the ordinary text-book description of the relations of the axillary artery to the cords of the brachial plexus. He quotes the following description from Quain: "First part of the axillary artery.—The nerves of the brachial plexus are to the outer side, the external anterior thoracic nerve crosses in front, and the internal and posterior nerves pass behind. Second part.-The three cords of the brachial plexus are placed one on the outer side, the second behind, and the third to the outer side." From Ellis he quotes as follows: "First part.—On the acromial side lie the cords of the brachial plexus. Second part .- In this portion the cords lie around the vessel, one being outside, another inside, and the third behind the artery." Mr. Whitaker then goes on to remark that it will be seen at once that it is impossible for the inner cord of the brachial plexus to lie on the outer side of the first part of the axillary artery and on the inner side of the second part without having passed either behind or in front of the vessel, and this must be the case if the usual descriptions are correct. As a matter of fact, the inner cord of the brachial plexus passes behind the axillary artery to gain its inner aspect, so that the relations should be stated as follows: "The cords of the brachial plexus lie to the outer side of the first part of the axillary artery, and at the junction of the first with the second part the inner cord passes behind the vessel and gets to its inner side, so that in the second part of the course of the artery the cords of the brachial plexus lie, the outer cord to its outer side, the posterior cord behind, and the inner cord to its inner side."

Inflammatory Hypertrophy of the Breast in a Case of Gynæcomastia.—At the February meeting of the Société des sciences médicales de Lyon, reported in the Lyon médical for April 22d, M. Hassler gave a further account of the case of a subject of gynæcomastia whom he had shown at the November meet-

ing. The patient was a soldier, twenty-three years old, affected with chronic mastitis, with enlargement of the axillary glands. Constitutional treatment with potassium iodide and local treatment by means of compression had been of no avail. The same was true of localized sweating produced by inunction with an ointment of pilocarpine, which in Mollière's practice had given very encouraging results in similar cases in women. The breast had been amputated, and the patient was now convalescent and about to resume military service. In about a month after the operation the axillary glands had ceased to be appreciable. The tumor had weighed nearly five ounces and a half, and presented macroscopically the characters of a very fatty mammary gland beset with hard kernels.

The Statistics of Surgical Anæsthesia.—In the Journal des praticious for May 2d Dr. Gurlt, of Berlin, is cited as callinics in Germany. The total number for the year 1892 was 100,000, and for 1893, 151,000. The mortality in anæsthesia by chloroform was fourteen times as great as in that by ether. Among twenty-six thousand persons who were anæsthetized with ether only one died, but in one thousand nine hundred and twenty-four cases of chloroform anæsthetization the mortality was the same. Gurlt attributes the successful use of ether to the prudence exercised by surgeons, and to the employment of the gentle method, which is superior to the so-called asphyetic method, and to the use of the mask, which is almost universally adopted in Germany.

The Diurnal Limits of Muscular Power.—The devotees of early rising will find little consolation in the experiments on muscular work which are reported by Dr. Vaughan Harley in the Journal of Physiology for March. The work done during a uniform number of voluntary muscular contractions was measured by an ingenious apparatus, and the results proved that more work could be done in the afternoon than in the forenoon. The kinds of food taken, as well as the periods of digestion, were found to have a marked influence on voluntary muscular energy. A periodical diurnal rise and fall in the power of doing muscular work was noticed, however, which was irrespective of the influence of food. The muscles are weakest during the forenoon, the minimum amount of muscular power being found about nine o'clock in the morning. The muscles are strongest during the afternoon, the maximum strength being reached at about 3 P. M. A normal diurnal fall in the muscular power was found, usually occurring about 5.30 P. M. The approach of fatigue was, however, noticeably delayed by regular exercise, which also increased both the size and the power of the muscles.

The Preventive Treatment of Seasickness.—Chlorobrom, which is a solution of chloralamide and potassium bromide, is the latest remedy proposed for the motion-sickness so terrible to many ocean travelers and railway tourists. From the results of its use in three hundred cases reported by ships' surgeons in medical charge of steamers plying between Great Britain and the United States, Canada, India, Australia, and New Zealand, Dr. M. Charteris, professor of materia medica and therapeutics in the University of Glasgow, reiterates in the Lancet of April 21st that chlorobrom, judiciously taken, will prevent an attack of seasickness, or cut it short if it has already begun. He states, however, that no prophylactic benefit can be secured by the use of chlorobrom in long sea voyages unless, for two nights before embarkation, the passenger depletes the stomach and bowels by taking a cholagogue pill. Persons who dread the voyage will be helped by a previous dose of the solution. On board the vessel the diet should be spare and dry. No full meal

should be indulged in, and soup, pastry, and sweets especially should be avoided, and a hypnotic dose of chlorobrom should be taken for three nights, a tablespoonful at a dose for women and a tablespoonful and a half for men. For short voyages, beginning about 10 P. M., the passenger should take one dose of the size mentioned and immediately go to bed. Immunity from seasickness is obtained in the great majority of persons if these directions are followed, but if they are not, the result will be that the chlorobrom will have no effect in arresting an attack of vomiting. Teaspoonful doses given every ten minutes until a tablespoonful or a tablespoonful and a half has been given, will. however, almost invariably check the retching and depression, which Dr. Charteris believes are due to irritation of the vomiting center in the medulla oblongata consequent upon the vomiting caused by the gastric disturbance due to the unusual amount and uniformity of motion.

## The State Board of Medical Examiners of New Jersey.

—A special meeting of the board for the examination of candidates desiring to practice medicine in the State will be held in the Capitol, at Trenton, on the third Tuesday of June (the 19th), and it will be the last meeting for the examination of candidates held under the present medical law, as the new law enacted at the recent session of the Legislature goes into effect on July 4, 1894. This new law requires all candidates to have a competent common-school education, to be graduates in medicine and surgery, which they shall have studied at least four years and upon which they shall have taken three full courses of lectures, before they can be admitted to the examination for a license, and then all will be subjected to the same examination; it also empowers the board to accept, in lieu of an examination, the certificates of other State examining and licensing boards having similar requirements.

The Various Forms of Blood Cells,-The classification of the corpuscles of normal human blood has been much expanded by Ehrlich, whose groupings are followed by Dr. W. S. Thayer in the Johns Hopkins Hospital Reports. The red corpuscles, the blood plates, and the colorless cells make three easily demonstrated kinds of corpuscles in human blood, but the colorless cells need to be subdivided into five varieties, according to their differing reactions to staining fluids. Lymphocytes are the small colorless cells approaching the red corpuscles in size, the body of the lymphocytes being filled with a large, round, deeply staining nucleus, while the protoplasm is represented by a small ring about the nucleus. Uninuclear leucocytes are larger cells, which have a relatively large amount of protoplasm. Transitional forms are those cells which have a similar appearance to the two foregoing varieties, but differ from them only by the nucleus showing certain indentations which may give to it the appearance of an hour-glass. Multinuclear neutrophiles are cells perhaps a trifle smaller than the large uninuclear elements, and having a single nucleus so irregular in shape that it may appear as several nuclei under a single focus of the microscope, thus forming a characteristic polymorphic nucleus, with a thick non-staining granulation. Eosinophiles usually have a polymorphous nucleus, and contain the larger and more refractive eosin-staining granules. The protoplasm of the lymphocytes usually takes a red-violet color with a triple staining, while that of the large uninuclear elements has but a slight affinity for coloring matters. There exist, however, in all human blood a number of uninuclear and some multinuclear elements, which have a protoplasm that remains entirely unstained, looking like a white spot or a small vacuole in the middle of the stained cell. Nucleated red blood cells, or normoblasts, are found in the bone-marrow. In pathological conditions there are many abnormal varieties of blood cells.

# THE OPERATIVE TREATMENT OF ACUTE SUPPURATIVE PERITONITIS.\*

By B. E. HADRA, M.D., san antonio (formerly of galveston), texas.

Not very long ago I was again in a position to operate for a general suppurative peritonitis in a dying patient whom I had not seen till then. I will not ventilate the question whether operative interference in this stage is justified or not. I think every surgeon has to settle this point for himself according to the existing circumstances. In this case I thought I had enough proof of perforation of a typhoid ulcer situated above the level of the umbilicus. Making the incision accordingly high up, I found an immense purulent accumulation pent up in the deep pocket below the right lobe of the liver, entirely shut off from the left and lower part of the abdomen by the distended bowels. After emptying it, it became evident that I had not found the starting-point of the inflammation. I then made the usual incision for appendicitis, and got to the seat of the trouble—a perforated appendix—during whose ablation the patient died. It was evident that the two cavities entered by the two incisions were not in communication with each other, and could not have been drained through one opening without breaking up considerable adhesions, or without unpacking the intestines. In fact, there was pus everywhere in the nooks and folds, the recesses and cavities, partially shut off by adhesions, partially free.

I do not maintain that this picture was anything unheard of; on the contrary, it is more or less the rule in such fargone peritonitic suppurations, and uncomfortably familiar to me. But once more the conviction came home to me that the present methods of wrestling with these formidable devastations are utterly inadequate, and that the record of almost absolute fatality will be broken only by the extraordinary coincidence of the most favorable circumstances, unless we can improve on our treatment. The same thought caused me to recommend a free incision from the ensiform process down to the symphysis, followed by lifting up the intestines so that they could be placed on the abdominal surface and be kept there until, by flushing and draining, the suppuration would come to a halt. While the principle appears to be correct, it is obvious that this plan can not work well in practice, for reasons which will become evident during further discussion. And, in fact, it was successful neither in a case I treated in this manner nor in the hands of some other gentlemen who informed me of their attempts. It was highly interesting to me to find, only a few days ago (in the Ctrlbl, für Chirurgie, No. 4, 1894), a similar plan reported on by two Swiss surgeons. They seemed to have made extensive bacteriological and pathological experiments to arrive at the very same device, adding, though, a kind of box in which the bowels are kept

swimming. Their two cases, however, I am sorry to state, did not fare better than all others.

Confronted again, only a few weeks ago, with a case of the same unfortunate condition—an acute general suppurative peritonitis following appendicial peritonitis-I found myself wanting in a well-founded and settled plan of procedure. Of course the appendix was to be removed and the abdominal cavity flushed; in short, I had to do what for the present is considered the best thing. Still, I felt that I would not be able to rescue my patient by such means. I may state that he grew so hopelessly feeble during the preparations for the operation that it was abandoned. He died in an hour or so, and only a few hours after I had seen him for the first time. This, my last experience, caused me to go over the field anew, and to hunt once more for points that could be improved on. I was happy enough to get a sufficient opportunity to study the anatomical conditions, as much as pertains to the subject, by the kindness and valuable help of Professor Keiller, of the University of Texas, and the ready assistance of Dr. Flavin, and I will take the liberty to submit to your critical deliberation a survey of my ideas and a plan of surgical procedure based on the results of my investigation.

The disease, as generally accepted, kills by the effects of poisonous substances which either upset certain parts of the steering machinery (the so-called centers), or interfere with the metabolic processes in the tissues. Whatever may be the real cause of death, it is evident that either the production of the poisons must be stopped, or their absorption, or both. The production of the poison never takes place within the uninvaded peritoneal sac. The septic material always has to get in from one or the other abdominal or pelvic organ, or it is carried there by operative or nonoperative accidents. It is obvious, then, that the starting point has to be removed or excluded. The diseased appendix, or the decaying gall bladder or tube, has to be taken out, intestinal perforations have to be closed, free septic material must be washed out, and so on. This is too plain to require more discussion. Unfortunately, though, the seed, once sown out, is constantly reproduced. It is true the vast surface of the peritoneal pouch is only to some extent a favorable field for its growth. We know. from clinical and experimental experience, the power of the peritonæum to resist and overcome a large quantity of poisonous substances. It will absorb them, perhaps become thickened, so that it may form dense partitions; in short, it will defend the body to such an extent that it will, even for years, keep great quantities of suppurating fluid with its micro-organisms pent up, not allowing them to do fatal harm. And especially is the omentum instrumental in this function. But, of course, there is a limit to its ability to cope with the intruders. Their quantity and quality may be such as to frustrate the peritoneal power of defense. Likewise the patient's general condition may be such as to make the fight hopeless from the outset. I am satisfied, however, that, if nothing else should interfere, the peritonæum would in most cases come out victorious. What, then, is it that paralyzes, almost in all cases under

<sup>\*</sup> Read before the Galveston County Medical Society, March 12, 1894.

consideration, its protective power? No doubt it is the constant inpour of new poison, even after the visible breaks are repaired, the decayed tissues or the effete substances removed. And these fresh invaders, after once a peritoni-. tis has been established, come from the bowels. It is satisfactorily proved that the weakened and softened intestinal walls are readily pervaded by microbes which have their habitat there or have been accidentally carried there. Thus germs constantly enter the irritated and suppurative peritoneal pouch, and keep up or even increase the pathological process. A circulus viciosus is then established; the original infection of the serosa leads to the imbibition and softening of the bowel wall, and this in return permits the intraintestinal germs to permigrate into the peritoneal cavity. The more they do it, the more peritonitis; the more of this, the more weakening again of the bowel walls, and so on. In addition, the early developing distention of the latter increases the pressure of the intestinal coils and of the peritoneal surfaces upon each other. The increase of the general pressure in the cavity drives the poisonous fluids more readily into the lymphatic apertures. But, outside of all this, the products of the poisonous substances taken up into the system are to a great extent excreted into the stomach and bowels, whence they are reabsorbed. They seem only then to acquire the full ability to destroy the vital functions of the body. This connex has been proved by experiments (Hitzig, Alt, and others) and by clinical experience. Now think of the enormous production of these toxines in a disease where the peritoneal surface is constantly engaged in producing pus, and think of the paralyzed condition of the bowels in which they must retain all the excreted masses, in order to understand the rôle the intestinal part plays in our disease. Perhaps many a case could be carried over the time of danger solely by attention to this one point.

It is obvious, then, that the bowels have to be freed of the distention, that they have to be cleared of the toxic substances and microbes, and that they have to be kept in the best possible condition for constant drainage. As you know, the present methods for this purpose are manifold. Some surgeons only puncture the bowels, of course a very insufficient manœuvre; others incise and wash them out, then close them again, which is more in the line of the laiddown principles. Only a very few (Henrotin) stitch the incision to the abdominal wall, so as to make a temporary fistula through which drainage and lavage can be established. They alone, in my opinion, do the right thing. The large intestine can be reached through the natural outlet by a long, large tube, which ought to have a number of wide openings, instead of only one or two at its end. Therefore, the small intestine ought to be incised; as it contains, together with the stomach, the bulk of the toxic secretions. At the same time, therefore, the stomach may be washed out, especially when vomiting has set in. The undeniable good effect of purgatives on incipient peritonitis is easily explained by their cleansing and disinfecting action, and proves the correctness of the views expressed. Similarly, the preparatory treatment for abdominal operations by purging and the administration of large doses of antiseptics, like bismuth, naphthol, etc., is based upon such principles.

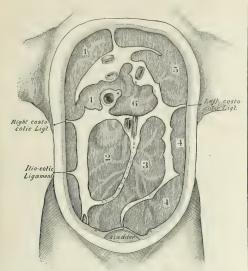

The second indication, preventing or lessening absorption of the poisonous fluids, is met by a removal of them from the peritoneal cavity. The idea of checking suppuration by germicides has been given up, as experience has shown that they do more harm than good. Flushing is thus employed simply as a mechanical cleansing, and nothing but sterilized water, perhaps with the addition of table salt (0.6 per cent.), the so-called physiological salt solution. which, according to the experiments of a German investigator, may prevent the formation of adhesions, should be used. Now we are taught to direct the current into every nook and corner of the peritoneal sac through the abdominal incision, to run our fingers into each fold and interspace, to break adhesions that may have formed, and to keep up with the thorough cleansing until the water returns clear. I protest against such a method, because I think that this very breaking up and stirring and handling is the best way to distribute the pus, to cause new traumatism, and to produce new wound surfaces, and thereby open new channels for the entrance of the poison-exactly what we try to avoid. The occasional experience of a rapid general sepsis following smaller operations on infected organs like, for instance, the womb, should teach us the dangers of such undertakings. I am perfectly satisfied that such interference in general peritonitis has more often contributed to the rapidity of the fatal end than delayed it. The formation of adhesions is one of the most important natural attempts at cure, and I think it is better to let even large closed pus pockets alone for the time being than to add that one straw to the camel's back, when nothing but keeping the patient alive should be aimed at. We know that such pockets may persist even for years. They are to be attended to later on. Therefore, I would put it down for my rule not to use the fingers more than is necessary, to gently insert the nozzle of the syringe into freely accessible folds and interspaces. Of course, such a flushing will not be very exhaustive, but I will explain presently how we can greatly increase its efficacy. The rule, however, should be kept in mind that every atom of unnecessary wounding and handling of peritoneal tissues should be avoided.

From anatomical reasons we have to expect accumulations of purulent fluids in front, between the anterior surface of the intestines, the omentum, and the anterior abdominal walls; next, between the intestinal coils, here perhaps shut off by adhesions. But before all, the fluids will settle from simple gravity in the most depending cavities and pockets on the posterior abdominal and pelvic wall, especially in the usual recumbent position of the patient. Erroneously the Douglas pouch is considered to be the common reservoir for all of the routes the fluids have to take, and, erroneously therefore, emptying it is all that many deem necessary.

On the first glance at the often reproduced diagram devised by Delépine, one finds that the insertion of the mesentery and the mesocolon, in combination with other peritoneal folds, partitions the abdominal cavity (considered from the diaphragm down to the true pelvis) into five well-

defined and separate pockets or drainage districts, and if the lesser cavity of the peritonæum is added, there are, in fact, six pouches which communicate with each other

June 2, 1894.]

After Delépine (slightly modified), to show the lines along which the peritoneum leaves the wall of the abdomen, and the pouches resulting from such an arrangement.

either not at all or only indirectly or partially. After examining these conditions with the friendly assistance of our distinguished anatomist in a number of bodies, I may describe these pockets in the following way:

Pocket 1.—This may be called the right perihepatic, as it is filled mostly by a part of the liver. It lies on the right side of the vertebral column, suspensory ligament of the liver, and the free margin of the gastro-hepatic omentum. It is bounded above by the diaphragm; below, by the right half of the transverse colon and great omentum, the hepatic flexure of the colon, and by a double transverse fold of peritonæum which runs from the upper part of the ascending colon outward to the right abdominal wall, a little below the top of the eleventh rib and as far forward. This fold is of varying breadth. There may be only a trace, or it may be one to two inches broad, so as to stand four to five inches above the deepest part of the pocket when the body is recumbent. The perihepatic pocket is, measured from the anterior surface of the bowels to its deepest point, at least a foot deep, and, of course, more when the bowels are distended. It is open above between the liver and transverse colon where fluids can escape by overflow. They could do so also sideways along the right lumbar wall, were it not for the fold described above, which will, when the bowels are distended, be lifted and pulled up sufficiently to partially close this route and shut off the pocket from the underlying pocket to be described directly.

Pocket 2.—The second pocket, which we may call the supracœcal, is bounded above by the transverse colon and incorrect.

mesocolon, the mesentery and the small intestine below and toward the left, and to the right by the cæcum and ascending colon and its mesentery if it be distended and swung by a mesentery; but if it be empty and flattened against the abdominal wall, the right boundary will be the parietal wall between the above-mentioned lateral fold and a similar fold which frequently extends outward from just above the cæcum to the lateral wall near the iliac crest. This cavity is considerably flatter than the first pocket, owing to the forward curve of the lumbar spine, but is sufficiently walled up all around to prevent escape of fluids in the recumbent position except by overflow.

Pocket 3.—The third pocket, the paracæcal, comprises the right iliac fossa, and, running upward, drains into Douglas's pouch along the right side of the sigmoid mesocolon and mesorectum.

Pocket 4.—The fourth pocket comprises the area below the left half of the transverse colon and its mesentery and to the left of the small intestine and mesentery. Its deepest recess in recumbency is just under the splenic flexure of the colon. It drains also into Douglas's pouch.

Pocket 5.—The fifth pocket may be called the left subdiaphragmatic. It is bounded above by the diaphragm, to the right by the suspensory ligament of the liver and greater curvature of the stomach, below by the transverse colon and great omentum, by the splenic flexure, and by a double fold of peritonæum—the costo-colic ligament.

Pocket 6.—The sixth pocket is the lesser cavity of the peritonæum, entirely closed as known, excepting Winslow's foramen, which will admit very limited communication of fluids.

In a cadaver whose abdomen is filled with fluid, we will find it accumulated in the first four-mentioned cavities, while the left subdiaphragmatic space and the lesser cavity of the peritonæum will not be entered by it, being too well partitioned off from the balance. As the third and fourth cavities, though, represent one system of drainage, with Douglas's pouch as a common reservoir, in which capacity it also serves for the free fluids in front of the bowels, it is mostly this pouch and pockets 1 and 2 which will contain the purulent masses. Thus it is seen that there are several entirely separate drainage districts, and that the idea of emptying all of them by one common channel or opening is utterly incompatible with anatomical facts.\* The real anatomical conditions are, on the other hand, an excellent arrangement for penning up the purulent material in the different pockets, and preventing an easy communication between them.

Now, at the beginning, the suppurative peritonitis will be limited to the immediate vicinity of the place of infection, say to the pouch it belongs to. As mentioned, the inflammation may remain local, the involved parts or the pouch becoming closed up by peritoneal, and especially omental, adhesions. But when the infection spreads it can

<sup>\*</sup> What we read in the Reference Handbook of the Medical Sciences, in an article by Frank Baker, that "the abdomen is divided into a right and left space, and an effusion upon the right will pass to the right iliac fossa only, while one on the left will descend into the pelvis," is incorrect.

do so by different routes or by a combination of some of them. First, the poison may pervade the softened bowel wall on points outside of the primarily infected pocket, because the same coil of bowel may be contiguous with different pouches. The second route of progress is by continuity in the peritoneal sheet itself. The third way is by infection through the purulent fluids which form on the anterior surface of the intestine or are lifted up there, whence they will get between the uninfected coils of bowels and finally settle in the most depending parts, the pouches infecting also their serosa. Under all circumstances, though, the originally infected pouch will be the most important object of surgical interference. It may be utterly impossible to make out which others have secondarily become invaded, and no doubt the term "general peritonitis" must not always be taken verbatim. It will practically suffice to know that one of the anatomical receptacles, and, before all, the anterior surface of the bowels, are suppurating. Still it will be of great consequence to have a general idea about which pockets are most likely infected before the operation; because, I state it again, it must be the rule to do the work with as little loss of time and as little cutting and breaking up as possible. In the great majority of cases we may pay little attention to pouch 5 and pouch 6 for reasons given, while, of course, they, under certain circumstances, will be the original seats of suppuration themselves. From such considerations we will do well to map out a certain scheme for surgical procedure according to the greatest probability with which we will encounter the original seat of the suppurative process by a direct route. I think that the following summary will be of some service:

Pouch 1 will surely be the primary seat of infection when this starts from the liver to the right of the suspensory ligament and gastro-hepatic omentum; from gall bladder, gall ducts, and the right superior wall of the transverse colon and of the hepatic flexure; possibly, in adhesive perforation of the duodenum, pylorus, and some parts of the stomach.

Pouch 2 will be primarily affected possibly in typhoid and other ulcers, and in traumatic injuries of the small intestine; also in such of the ascending colon, the superior wall of the execum, and perhaps also in duodenal suppurations.

Pouch 3 has to be entered in appendicial diseases and disorders of the genital organs and bladder; also, in suppurations starting from the rectum, sigmoid flexure, and the small intestine.

Pouch 4, in suppurative processes originating in the small intestine, sigmoid flexure, descending colon, and rectum.

Pouch 5, in suppurations starting from the left lobe of the liver, spleen, anterior surface and left side of the stomach with certainty.

Pouch 6, from such originating in the posterior wall of the stomach, a part of the transverse colon, and by adhesive perforation from the pancreas, pylorus, and duodenum.

The first two pockets can be entered from the same incision along the anterior border of the right quadratus It will be always found in the same relation to the execum,

lumborum in a line from the brim of the ribs to the anterior superior spine of the ilium. If repair or removal of diseased tissue is intended in pouch 1, the incision will be better made transversely along the lower anterior border of the liver, which is the landmark of this pouch. Pouches 3 and 4 can be opened together by a median incision below the umbilicus, or by one more to the right—the usual incision for appendicitis, for instance.

Pouch 5 will be best found by an incision along the thoracic outline from the termination of the eighth or ninth rib to that of the eleventh or twelfth. The left lobe of the liver is the guide here for the examining finger.

Pouch 6 can be entered by a transverse incision through the omentum between the stomach and the transverse colon, or by way of the fifth pouch, sideways or from behind

In order now to do thorough work, we shall not feel satisfied with flushing one pouch alone, if clearly more than one is the seat or receptacle of purulent material. Before all, it seems to me absolutely irrational to make a median incision below the umbilicus the general rule. Where, for instance, the left subdiaphragmatic pocket or the lesser cavity of the peritonæum, or even the perihepatic pouch, is involved alone, it is almost criminal to open the natural protecting walls toward all other cavities. The median incision can only be the right thing when we seek access to the pockets numbered 3 and 4 and perhaps for No. 2. We must conform the mode of entrance to the seat of the main trouble, and must make as many openings as necessary to get to every infected pocket. Common sense will further dictate that the flushing should be extended into a continuous drainage until the danger is overcome. Evidently such can not be done by a short tube. I think the most reasonable method is to carry syphon tubes into as many pouches as contain pus, so that the fluid could be raised from the deepest points without much manipulation. I would therefore advise the plan which is already used for pleural drainage known as the Buenau method.

Now, to illustrate my propositions, I will describe the proposed treatment for peritonitis due to appendicial perforation, which will be materially the same as for all generalized suppurations originating somewhere outside the fifth and sixth pouches. This plan may appear very complicated and meddlesome, but it will do so, I trust, only at first sight.

Be careful not to make much display and unnecessary ado around the patient. Do not scare him and all the relatives to death before you begin. There is full sepsis already present and the patient need not be sent through 'all the aseptic cleaning ordeals. In some cases you may operate on the bed with no more preparation than a waterproof sheet which you will push under the patient. Use nothing but sterilized water, perhaps the mentioned salt solution. Now, attend to the removal of the appendix, making the incision at the well-known place of selection; but be careful not to get into pouch 2, keeping always to the inferior wall of the cæcum. The appendix always belongs to pouch 3, where it will mostly have a little side pocket of its own. It will be always found in the same relation to the cæcum,

and consequently to the second pouch, even if it should have been dragged far away by adhesions. It may be that the suppuration is entirely confined to the third pouch. If there be free purulent fluid on the surface of the bowels it will burst forward unless omental adhesions prevent it. In this latter case do not use any force in breaking them up. Seize the next knuckle of small intestine, make an incision one inch long into it, and wash out the gut in both directions with sterilized water, to which tannic acid as the most effective and least dangerous germicide may be added. Then stitch the intestinal incision into the upper angle of the abdominal incision by a few silk stitches, so as to establish an intestino-abdominal fistula. The tympanites will have greatly subsided, and you can now easily flush the abdominal cavity in front, if you want to, but be tender and do not break adhesions. But perhaps it will be best not to do any flushing at all. Next, insert the one end of the siphon tube (as it is used for washing the stomach) deep down into Douglas's pouch, and close the abdominal incision tightly around it at the lower angle and between it and the opening of the fistula. Secure the tube by a stitch to the skin. Now make an incision about two inches long on the anterior border of the right quadratus lumborum muscle only down to the internal fascia, beginning at the tip of the eleventh rib and carrying it down toward the outer superior iliac spine; perforate by knife or a dull instrument the upper end of the incision so as to get to the liver. You are then in pouch 1. Wash it out and insert a siphon tube, securing it again by a stitch to the skin. Make another perforation in the same incision through a point at the level of the umbilicus, and you are in pouch 2. Treat this the same way as No. 1, inserting a third siphon tube; close the incision around the second tube. Now have the free ends of the three siphon tubes submersed in some kind of an aseptic fluid in vessels put on the floor near the bed. Satisfy yourself of their working, and, if necessary, wash the cavities out through them by raising them and pouring sterilized water in through a funnel. It may be advisable to flush the intestines through the fistula at least once a day with a tannic-acid solution, otherwise keep the fistula protected by a cotton pad smeared with borated vaseline. Let the patient keep, if possible, a semi-recumbent posture. In this way all the main pockets can be drained and flushed, the bowels washed out, while no opened wound has to be attended to except the fistula, which, of course, will have to be closed afterward.

It is true that this plan will not suit every case of purulent peritonitis, but there is no reason why it should not be adapted to the circumstances. For instance, when pouch 1 is the seat of the original trouble, a transverse incision may be made over it, and then a small incision for the drainage of Douglas's pouch and for the intestinal fistula added. When for intestinal perforation a large median incision has become necessary, the three holes for the siphons may be made from the inside and the tubes pulled through, and the median incision closed, except, again, for the fistula. For suppurations in pouches 5 and 6 most probably no other but the originally infected one will have to be entered and kept drained. In cases, finally, in which the operator may

feel satisfied with ridding the whole abdominal cavity of its purulent contents by only one thorough flushing, it has to be kept in mind that all the four pockets have to be attended to. The nozzle of the syringe may then follow the carefully and gently progressing fingers under the right lobe of the liver, then to the right of the umbilical transverse line, and finally down into Douglas's pouch, whence the current should be directed upward to the right and left of the sigmoid mesocolon into pockets 3 and 4. In case the siphon tubes should not be on hand, common rubber tubing of about half an inch in diameter and four to five inches in length may be employed. If the free end is submerged in a fluid and the air squeezed out of the lowest part of the tubes, they will become siphons.

Now, I am aware that my plan will, at best, be but one step forward, one of the many that have to be made before we will be able to cope successfully with so formidable a foe. There are many more factors to be considered than those named. The deleterious effects of the poisons upon brain, heart, kidney—in fact, upon the whole system—thrombosis, embolism, softening, and so on, may frustrate even the most perfect surgical method. Still, we should not let our hands sink in despair. If we learn to save one more out of a hundred, even that little is worth battling for.

#### APPENDIX.

Shortly after this paper was read I had a chance to test that part of it which pertains to the establishment of the temporary intestino-abdominal fistula.

Six weeks previously I had removed the uterine appendages of a virgin twenty-two years old. From inexplicable causes infection, especially of the abdominal parietes, followed. The walls of the incision sloughed and the patient lingered along with a slow elevation of the bodily temperature in the evenings. A vaginal examination revealed a mass in the right parametrium, which was thought to be an accumulation of pus. It was decided on to reopen the abdominal wound, which anyhow held together seemingly by granulations only, and to wash out the pus. But the mass turned out to be a suppurating lump of omentum firmly glued to the pelvis and to the right appendicial stump and the surrounding surface of the womb. It was not possible to detach it from the latter without causing an extensive removal of the serosa, and, as the womb was flaccid and looked injected and angry, it was deemed best to remove it at once, to get rid of this source of danger, as well as to get better drainage. This was done without much difficulty. On the second day evident signs of peritonitis set in, the temperature rose to 102° F., the bowels became distended, the pulse quick and small. There was constant retching. All attempts to move the bowels failed. Next day the case looked hopeless. The tympanites was excessive, the temperature reaching 103° F., and the general condition extremely threatening. I then reopened the abdominal incision once more. A large amount of discolored bloody serum with some pus flakes welled up. The walls of the intestines presented a bluish-red coloration, and occasional fibrin flakes were noticed on them. The next knuckle of small intestine was incised and, after a quantity of gas and very little fluid had escaped, the gut was stitched to the abdominal wall. Then the abdominal incision was closed, this being done about nine o'clock in the evening, after which I had to leave town and did not return until ten o'clock the following morning. I was not a little surprised to find my patient in a most satisfactory condition. The temperature was subnormal, the pulse steady though over 90, abdomen flat, no nausea. A few hours after I had left a copious discharge from the fistula had set in; in fact, it was so free that when I made my next visit I found the patient lying in a pool of that discharge. It was a dark, grumous fluid mixed with threads, in short, of the same nature as we are used to see it in peritonitic vomit after the purely bilious secretions have stopped. There was a continuous welling up. The next day the discharges became more fæcal and solid. They soon after stopped flowing, and at once the patient began to complain of pain and grew uneasy. All this was easily remedied by an injection of warm water through the fistula, which revived the flow. The patient improved so quickly and was in so satisfactory a condition that five days after the establishment of the direct intestinal drainage the fistula could be closed. The brittle condition of the bowel wall, though, prevented a perfect primary healing; there remained a small opening, permitting the escape of fluids, but it is to be hoped that this also will soon close. Otherwise the patient is in good condition.

This case is very similar to the two cases reported by F. Henrotin,\* of Chicago, and I think they are as good proofs of the correctness of the view expressed as could be wished.

I may be permitted to add a few words in regard to minor technical points. The incision in the gut, I think, is best done before stitching it to the abdominal wall, because the circumference becomes so much smaller that the previous stitching will make the lips pucker a great deal. As it must be advisable to close the fistula with as little difficulty as possible, it seems to be best to leave at least three fourths of an inch between the lips of the fistula and the line of the abdominal suture; or, in other words, to pull the intestinal knuckle high up into the incision before securing it. When it has then to be closed there will be sufficient room on both sides for a double row of Lembert stitches. In regard to the detachment of the gut from the parietal peritonæum, it may be that it is not necessary at all and that such adhesions may be entirely innocuous. Still, I think the surgeon will feel better satisfied if he knows that everything has been returned to natural conditions. Perhaps, then, it will be a good plan to surround the fistula with a ring of gutta-percha tissue or some similar unirritative material before stitching, so as to have the foreign body interposed between the two peritoneal surfaces. When the surgeon then has closed the fistula, he would, after a few days of satisfactory watching, have nothing else to do but to clip the sutures, remove the tissue, drop the gut, and close the abdominal incision.

The Obstetrical and Gynæcological Society of Berlin.— The Centralblatt für Gynākologie for May 12th announces the completion of fifty years of activity by this society, which, it says, is the oldest of its kind in Germany.

The late M. Diday.—The Lyon médical announces that Dr. Diday left three thousand francs to the Association of Physicians of the Rhone and a thousand francs to the General Dispensary.

ON THE ALLEGED SPECIAL LIABILITY OF BENIGN LARYNGEAL GROWTHS TO UNDERGO MALIGNANT DEGENERATION AFTER INTRALARYNGEAL OPERATIONS.

By FELIX SEMON, M.D., F.R.C.P.,
PRESIDENT OF THE LARYNGOLOGICAL SOCIETY OF LONDON.

WITH AN APPENDIX

By DAVID NEWMAN, M.D., PRESIDENT OF THE PATHOLOGICAL AND CLINICAL SOCIETY OF GLASGOW.

The purpose of the following communication is to correct before the American medical profession a series of very grave misstatements made by Mr. Lennox Browne, of London, in a recent American work—viz., Burnett's System of Diseases of the Ear, Nose, and Throat. These statements are intended to support his views on the special liability alleged by him of benign laryngeal growths to undergo malignant transformation after intralaryngeal instrumentation.

I had hoped that the indignant protest against Mr. Browne's methods of argumentation raised by Mr. Shattock and myself in our Sequel of a Case of Anomalous Tumor of the Larynx, read before the Pathological Society of London, on December 19th of last year, and published in abstract in both the British Medical Journal and the Lancet of December 23d of that year, would have become sufficiently known in America to enable me to dispense with the very unpleasant task of exposing in America itself the fallacies and misrepresentations to which Mr. Browne has resorted. This hope, however, has unfortunately not been realized. On my return from the International Medical Congress at Rome I found a letter from an American laryngologist, Dr. Pearce, of Chicago, stating that the writer was surprised to find in Mr. Browne's article the assertion that I had changed my views, or rather that I was now included among the supporters of Mr. Browne's theories. Dr. Pearce then asked me whether this assertion was really true.

In view of this question it becomes unavoidable, I feel, in the interest of the important scientific point at issue, to ask for the hospitality of a leading American medical journal in order to expose the methods by which Mr. Browne attempts to support his ideas.

No effort will be made in the following lines to enter upon the numerous merely controversial statements contained in Mr. Browne's article.

A few stern facts will be submitted to the judgment of American readers, which can be easily verified by any one interested in this question. Not much comment will be needed, because these facts speak eloquently enough for themselves, and I shall leave the judgment as to Mr. Browne's ethics to the reader.

The charges which I bring against Mr. Browne are as follows:

1. That he has in his chapter on Deformities and Morbid Growths of the Pharynx and Larynx, in Burnett's work, when discussing the question of transformation of benign laryngeal growths into malignant ones, grossly misrepresented the views and statements of the late Sir

<sup>\*</sup> Enterostomy and Drainage in the Treatment of Diffuse Septic Peritonitis. American Journal of Obstetrics, August, 1893.

Morell Mackenzie, and distorted several of that author's cases.

- 2. That he has on the same occasion, in what he states to be an exact quotation from the report in the British Medical Journal of a paper of Dr. David Newman's, substituted at the crucial point an expression of his own for that used by the author, and has thereby entirely perverted the latter's statement and meaning.
- 3. That he has again on the same occasion not only suppressed material facts in connection with Mr. Shattock's and my own case mentioned in the beginning of this communication, but has on the strength of his suppressions grossly misrepresented my views on the question under discussion.

After attempting to discredit the results of my collective investigation concerning the question of the transformation of benign laryngeal growths into malignant ones,\* Mr. Browne asserts † that the late Sir Morell Mackenzie, in his essay on Growths in the Larynx, thad arrived at very different results, and had "candidly accepted" in his one hundred cases three as "having assumed malignancy after having been treated as benign, because repeated microscopic examination by several eminent pathologists had justified their inclusion in that category."

This assertion is absolutely untrue. Not one word will be found on the page (page 97) of that work quoted by Mr. Browne, nor indeed in the whole work, making any such admission with regard to three of the one hundred cases. On the contrary, nine years later Sir Morell Mackenzie, in his chief work, Diseases of the Throat and Nose, vol. i, 1888, has stated in the most unequivocal terms (page 317) that in his own practice he has seen one case only in which a growth originally benign afterward assumed a malignant character, and that he was not aware that there was the slightest evidence that in any one case treatment had exercised an unfavorable influence.

To enable the reader to compare Mr. Browne's and Sir Morell Mackenzie's statements, I append them here verbatim in parallel columns.

MR. LENNOX BROWNE.

the Ear, Nose, and Throat, vol. ii, 1893, p. 768.)

"A very different experience from that of Semon may of the conversion of benign be deduced from the very frank into malignant growths, I may statistics of Morell Mackenzie, mention that in my first series for, with regard to recurrence, of growths there was one case he relates that out of ninetythree cases treated through the be papillomatous, but subsefauces, six recurred which had quently proved to be an epibeen entirely extirpated; in thelioma. (Burnett's System of Diseases of (Diseases of the Throat and Nose, vol. i, 1890, p. 317.)

"As regards the question which at first was believed to was effected the growth after in my work, the patient's throat

a time underwent further development, and in one case this is not all. Three out of Mackenzie's one hundred cases assumed malignancy after having been treated as benign, because repeated microscopic examinations by several eminent pathologists had justicategory."

was so irritable that only three séances were attempted, and I the growth persisted. But only once succeeded in passing forceps into the larynx. As the whole growth was subsequently are candidly accepted to have removed by thyreotomy, I can not imagine that a single endolaryngeal operation should have converted a benign into a malignant growth. The whole subject has recently been so ably fied their inclusion in that discussed by another physician\* that I can not do better than make use of his observations. While allowing that benign growths sometimes assume a malignant character in the entire absence of surgical interference, the writer calls attention in this respect to Virchow's t opinion, who admits that persistent irritation of healthy tissues may lead to the formation of heteroplastic growths. The author justly maintains, moreover, that the degeneration of benign into malignant neoplasms never takes place except when there is the inclination to constitutional vice, and he points out that under these circumstances the change may take place with or without surgical interference.

"He further remarks that even frequently repeated local irritation does not produce degeneration. This has been most noticeable in those cases in which, in consequence of repeated recurrence, laryngoscopic treatment has had to be recommenced de novo many times, sometimes even on four, five, or six occasions, until finally complete cure was ob-

"In some cases of growths, especially in recurrent papillomata, I have operated from time to time for many years without ever observing any malignant degeneration. Indeed, in the many hundred cases of papillomata that have been operated on, I only know of three instances (Gibb, Mackenzie, and Rumbold) in which growths originally benign afterward assumed a malignant

character. I am not aware that there is the slightest evidence that in any one case treatment exercised an unfavorable influence."

No comment is needed!

I now have to analyze the alleged three cases of conversion that have occurred, according to Mr. Browne's assertion, in Sir Morell Mackenzie's practice.

Mr. Browne says (loc. cit., p. 768):

"One case which was diagnosticated as a papilloma was that of a gentleman, aged forty-seven years, from whom Mackenzie removed several portions by the mouth, but severe stenosis following, thyreotomy was performed and the growth was radically extirpated. Six months later the patient died from malignant recurrence."

On referring to Sir Morell Mackenzie's work (*Growths in the Larynx*, p. 183) the reader will find that this case was described, not as a papilloma, but as an epithelioma by the author himself, who concludes his description *verbatim* as follows (*loc. cit.*):

"The fact that during life it was believed to be and was treated as benign had led me to include it among these cases, and having done so before repeated microscopic examinations had succeeded in discovering any cancer elements, I did not think it fair to exclude it afterward."

The reader will judge from this how far Mr. Browne's statements as to this case are justified.

Concerning the second case, Mr. Browne says:

"Another\* was considered by Mackenzie to be a simple adenoma of specific origin and benign nature, notwithstanding that a sub-committee of the Pathological Society appointed to examine the specimen considered it a case of 'adenoid carcinoma.' Nevertheless the after history of the case was such that nine years later Mackenzie described and figured it as a malignant growth."

I need not point out that, according to Mr. Browne's own description from this case, only one conclusion can be drawn—viz., that the sub-committee of the Pathological Society appointed to examine the growth was right and the observer mistaken in their differing opinions concerning the growth. Under no circumstances had Mr. Browne the right to quote this case as one of conversion from a benign into a malignant growth.

Concerning the third case, Mr. Browne says verbatim as follows:

"A third very striking example is one also exhibited at the Pathological Society of London (Pathological Society's Transactions, vol. xxi, 1870, p. 51) as a papilloma of the larynx, but being attached to the pharyngeal aspect of the cricoid cartilage, it has already been considered by the present writer under the more appropriate heading of pharyngeal neoplasms. This growth was believed by Mackenzie to be benign, an opinion which was confirmed by the Morbid Growths Committee; but this also was described and again figured by him ten years later as a malignant sarcoma."

With regard to this case I beg to observe:

- That the growth was admitted by Mr. Browne himself not to be an intralaryngeal one at all, and that any reference to it in the present connection therefore is absolutely misleading.
- 2. That the case was not exhibited, as Mr. Browne tells his readers, as a "papilloma of the larynx," but that its title, as given by Sir Morell Mackenzie himself (Trans. of the Pathological Society, vol. xxi, p. 53), is Large Tumor removed from the Posterior Surface of the Cricoid Cartilage.
- 3. That in Mackenzie's description of the case there is no word to be found as to his "belief that it was benign," as asserted by Mr. Lennox Browne.
- 4. That the report of the committee appointed, signed by Mr. Howard Marsh and Dr. Moxon, with regard to the histological structure of the growth, refers to the fact that the "central part of the papillæ is made up of a richly nucleated tissue, the nuclei being not more than a quarter of the size of those of the epithelial elements; fibrils connect these and blend to form a sarcous tissue (?) in which large blood-vessels are imbedded," and then goes on to say: "From a structural point of view we should call the growth a papilloma; the transitional forms between epithelium and sarcous tissue (growing alveolar in the subepithelial portion of the growth) throw doubt on the simplicity of the plan and raise proportional probabilities of its recurrence."

(The sarcous tissue in the center of the papillæ is also figured in Plate I, Fig. 1, of the volume just quoted.)

The reader, therefore, will be able to judge for himself how far Mr. Browne's description of this case as a very striking example of the conversion of a papilloma into a sarcoma is justified.

Mr. Browne continues (loc. cit., p. 769):

"It was the knowledge of the after history of these cases as well as one or two others of the same series (the details of which have not been published) that at first awoke my mind to the possibility of the conversion of benign into malignant growth." . . .

I have, I think, shown that these statements are absolutely incompatible with those of Sir Morell Mackenzie himself and with the facts of the cases reported; and I think it simply right in conclusion of this part of my paper to emphasize the fact that Mr. Browne, who has more than once been challenged to substantiate his assertions, and who at last, in 1887 (British Medical Journal, 1887, vol. i, p. 1816), gave his own list of the instances in question, has neither in that list nor on any other occasion in the twenty-three years which have elapsed since the publication of Sir Morell Mackenzie's first work, once claimed the cases to which he now attaches so much importance.

Now, however, that Sir Morell Mackenzie is gone and can no longer protest against the unwarrantable use made of his cases in clear contradiction to his own plain statements, Mr. Browne attempts to play him out, not merely against myself, whose views on this whole question Sir Morell had so unreservedly accepted (see above), but also against the accumulated experience of the great majority

<sup>\*</sup> Op. cit. | Case 88, p. 186.

<sup>†</sup> Op. cit., p. 350.

of the leading laryngologists of the world, collected nearly twenty years after the publication of Mackenzie's essay.

II.

After having utilized Sir Morell Mackenzie's cases in the manner described, Mr. Browne goes on to claim a case reported by Dr. David Newman (British Medical Journal, vol. i, 1889, p. 133) as "very striking in the direct relationship between the operation and the malignant transformation." Dr. Newman himself, as will be seen from his description in the British Medical Journal, brought forward this case, not as an example of the conversion alleged by Mr. Browne, but with the view of showing that "while conscious of the value of removing portions of a laryngeal neoplasm for diagnostic purposes, the proceeding should not be resorted to in cases suspected to be cancer [! F. S.], unless the patient is willing to have a radical operation performed immediately that the diagnosis has thus been completed," Inasmuch, however, as Mr. Browne would certainly have been entitled to draw a conclusion from a case different from that of the observer himself, no objection could be raised against his interpretation, if he had not unfortunately had recourse to a proceeding which can not be otherwise characterized than as a direct perversion of Dr. Newman's statements.

Mr. Browne (loc. cit., p. 769) quote's Newman's description as given in the British Medical Journal, and concludes this by saying verbatim (ibid.):

"The reporter, whose exact words have been quoted [the Italics are my own—F. S.], deduces from this case the conclusion," etc.

The crucial sentence in the quotation is in Newman's words the following:

"The subsequent course of the case proved them [viz., some enlarged lymphatic glands—F. S.] to be carcinomatous in their nature, and the growth within the larynx, which on examination of the first specimen was believed to be a papilloma, ultimately on examination of subsequent specimens proved to be an epithelioma, and the patient died from the disease."

On comparing, however, the original sentence in the British Medical Journal with that given in Mr. Browne's description, the reader will find that for the word "believed" Mr. Browne has simply substituted the word "demonstrated," and thereby entirely altered the sense intended by the author! The substitution is maintained in the concluding sentence of the paragraph referring to Dr. Newman's paper, in which Mr. Browne again asserts that the conclusion of the diagnosis was supposed to have "demonstrated" in this case the innocent nature of the growth. On the strength of this manipulation Mr. Browne dares to claim in his concluding paragraph on the next page that to his list of more or less willing adherents to his conclusions must now be added Dr. David Newman's name, together with my own.

#### III.

"But the strongest case of all," Mr. Browne continues (loc. cit., p. 770), "is one related by Semon himself, and already referred to under the head of benign angelomata. In this case the trans-

formation is so vividly illustrated that details of the subsequent history are most instructive, and the more so since they have not appeared in the journal in which the case was first reported. In the opinion of Massei and Malebranc, the growth was 'an angeioma, possibly of ancient date but of recent development.' Semon, in his clinical account of the tumor, remarks: 'There was no enlargement of the glands in the neck and no evidence of malignancy; in short, I entirely agreed, from what I had read in laryngeal text-books of that extremely rare form of laryngeal tumor-angeioma-but of which I had never seen an instance, that the growth was in all probability of this character.' A supplemental report in another journal states that the tumor, which on removal by the galvano-cautery snare was found to be an innocent papilloma surrounded by blood-clot, recurred four months and a half afterward, with the same external appearances. The new tumor was removed in its greatest part per vias naturales, and microscopic examination revealed that it was of the same nature as the original, but near the base existed epithelial cones projecting into the

"After Mr. Shattock and Mr. Butlin had pronounced the diagnosis of malignancy, the rest of the neoplasm was removed by subhyoidean pharyngotomy. On the evening of the fourth day after operation, the patient died comatose. Further examination of the tissue removed by the external operation left no doubt as to its malignant nature.

"Whether, in this or any other cases, the malignant transformation be the result of irritation caused by more or less partial evulsion, or whether it be that some of the papillomata, adenomata, or angeio-myxomata of the larynx are to be classified under the head of 'quiet cancers,' the fact remains that instances of the malignant conversion of each of these varieties of growths (within the larynx) have been admitted by Schnitzler, Seiler, Seifert, Solis-Cohen, Tauber, Wagner, Jarvis, Morelli, Blane, and others, and to this list of more or less willing adherents to the author's conclusions must now be added the names of Felix Semon and David Newman."

It is not easy to correct in a few words the misrepresentations of which this whole description is made up. The facts are simply as follows: The patient in question was sent to me by Dr. Malbranc, of Naples, with a letter in which that gentleman stated that he and Professor Massei, of Naples, had arrived at the diagnosis of angeioma of the larynx. My own examination appeared to fully corroborate that result. Even after removal the growth looked entirely like an angeioma, and Mr. Shattock and myself were not a little surprised when microscopic examination revealed that it was an apparently typical papilloma incased within an extravasation of blood. The coagulum had entirely concealed the cauliflower-like proper tissue of the tumor, and had given it the appearance of a globular mamillated growth. The proper tissue of the tumor was remarkable for its delicacy, and in this resembled the papillomata of the bladder rather than those commonly met with in the upper air-passages. (This last sentence is quoted from our first description of the case in the Transactions of the Pathological Society of London, vol. xlii, 1891, p. 392.) Our final conclusions, when reporting this case to the Pathological Society of London, were verbatim (loc. cit.) as follows:

"1. It is extremely rare to find a papilloma springing from the arytano-epiglottidean fold unless there be almost a univer sal papillomatous disease of the laryngeal mucous membrane. In the large number of papillomata which I [F. S.] have seen I have never come across a solitary papilloma in a similar situation

"2. The occurrence of spontaneous haemorrhage from a laryngeal papillona is, so far as our experience and knowledge of laryngological literature go, unique. Although analogous growths in the bladder regularly give rise to spontaneous hæmorrhage, no single instance of a similar occurrence in the larynx has to our knowledge ever been described.

"3. The formation of a complete casing of blood-clot about a papilloma, so changing its clinical character and simulating the appearance of an angeionna, is equally unique, and will have to be kept in view by future observers."

At the time of our first description there was no evidence, either clinical or histological, of this growth being malignant, and we therefore did not refer to that contingency. Nevertheless, in view of the patient's age, the unusual situation of the growth, and the occurrence of the spontaneous hemorrhages, we considered it more prudent not to commit ourselves to too definite an opinion as to the actual nature of the growth, and therefore, instead of describing it as an Unusual Case of Papilloma of the Larynx, or giving it a similar title which would have bound us to the opinion that the growth belonged to the category of benign laryngeal tumors, deliberately chose the uncompromising title, Anomalous Tumor of the Larynx, under which it is published in the Pathological Society's Transactions.

From the foregoing facts it is obvious that Mr. Browne had no right whatever to speak of this case as one of "benign angeioma." It has never been described under that title, and Mr. Browne has simply availed himself (loc. cit., p. 760) of the fact honestly recorded in the clinical history viz., that the growth had been originally mistaken for an angeioma-to inform his readers that the "microscopic investigation entirely upset the diagnosis formed after laryngoscopic observation," In both his descriptions, however, he has absolutely suppressed not only our final conclusions, but above all the significant fact that already in our very first description we had given our communication the title of Anomalous Tumor of the Larynx, a fact which would have shown every unbiased reader of Mr. Browne's descriptions that the authors did not wish to commit themselves to any definite opinion as to the histological character of the growth.

This suppression is bad enough, but what follows is much worse. Mr. Browne describes the further history of the case from a brief preliminary report given in the Centralblatt für Laryngologie, etc., seven months after our first description,\* and winds up not merely with the assertion, taken by him as an indisputable fact, that in this case a transformation had occurred, but with the simply incredible declaration that I myself must now be added to his list of more or less willing adherents to his conclusions. Considering that I have devoted an enormous deal of labor, with the assistance of most of the leading laryngologists of

the world, in proving to the satisfaction of probably every laryngologist in the world, except Mr. Lennox Browne, that his so-called conclusions are utterly untenable, this last declaration in itself surpasses in boldness of conception all his previous achievements in that direction; but what will the reader say when he learns that the annotation in the Centralblatt from which Mr. Browne has culled his description of the further history of the case ends verbatim with the following sentence (Centralblatt, vol. viii, p. 318):

"That the new growth in this case was primarily [this word is printed in Italics also in the original] malignant, and can not in any way be looked upon as an example of transformation of a benign into a malignant tumor, appears to be unquestionable, and finds further corroboration by the various points enumerated above."

("Dass die Neubildung in diesem Falle primär bösartig war, und nicht etwa als Beispiel des Uebergungs einer gutartigen in eine bösartige Geschwulst betrachtet werden kann, ist wohl unzweifelhaft und findet durch die genannten Momente weitere Stützen.")

Mr. Browne calmly suppresses this entire sentence, and on the strength of his suppression dares to claim me as an adherent of his views!

When the sequel to the case was in December last brought before the Pathological Society of London, Mr. Browne in the discussion at first defended his views. But when all the speakers in the discussion-i. e., Messrs. Butlin, Victor Horsley, and Bowlby-had expressed their agreement with Mr. Shattock's and my own views as to the primary malignancy of the growth, and after Mr. Shattock had once more from the histological point of view shown that it was simply impossible to come to a conclusive opinion as to the histological character of the growth from the microscopic examination of the projecting part first removed, Mr. Browne suddenly declared (British Medical Journal, December 23, 1893, p. 1337) that "after the record of the subsequent histological examination he withdrew his previous statements as to the present case being an instance of the transformation of a benign into a malignant formation."

Be it observed this was "the strongest case of all" (Lennox Browne, loc. cit., p. 770), and the one on the strength of which Mr. Browne, in a manner fortunately almost unheard of in scientific controversies, dared to misrepresent the opinions which I have unwaveringly held since, in 1878, I first took part in the discussion.

How bad must a cause be when it requires to be defended by such means as those employed by Mr. Lennox Browne!

39 WIMPOLE STREET, CAVENDISH SQUARE, C. T.

#### APPENDIX.

Dr. Felix Semon has submitted to me the foregoing paper in manuscript, and I desire to say that my views regarding the possibility of malignant transformation of benign tumors of the larynx are the same as his own, and not, as Mr. Browne assumes, that I accept the conclusion he has come to. When Mr. Browne succeeds in proving by

<sup>\*</sup> A full description of the further history of the case and of the histological features of the growth will be published in the forthcoming volume of the Transactions of the Pathological Society of London.

facts, not by misquotations, that benign growths are liable to undergo malignant transformation, then I may change from my present position, which is, first, that Mr. Browne has entirely failed to prove that a benign growth is likely to undergo malignant transformation as a consequence of intralaryngeal interference; second, that he has absolutely no right to claim me as an adherent to the opinions expressed by him; and third, that the facts published by authors are not consistent with the theory he tries to demonstrate.

David Newman.

### PNEUMONIA OF THE AGED.\*

By J. H. PRYOR, M. D.,

BUFFALO, N. Y.,

PHYSICIAN TO THE ERIC COUNTY HOSPITAL

THE title, Pneumonia of the Aged, is used in contradistinction to Pneumonia in the Aged. The essential differences between the two clinical types were recognized and carefully described by the older clinicians, notably Grisolle and Trousseau. The distinction established by the two terms has been preserved, as it promotes the object of this paper. Any argument in support of the use of the term "pneumonia of the aged" seems unnecessary at this time. It has been called asthenic, latent, and senile, with reference to its peculiar symptomatology. Latent pneumonia occurs as a complication of various conditions and diseases, and the term senile pneumonia is employed in a manner too broad to encourage proper discrimination. Pneumonia affecting the aged may be characterized by the usual clinical history of the disease as manifested in earlier years, and resembles the so called sthenic or frank type. It attacks the strong and well-preserved individual and is accompanied by re liable indications for diagnosis. The extreme type is not common, but corresponds with the affection in middle life. This form has been designated as pneumonia in the aged. Compared with pneumonia of the aged we notice varying degrees of dissimilarity, and the reason becomes apparent why the latter has been considered as belonging to a distinct clinical variety. To avoid the dangers of drawing fine distinctions and differentiating too arbitrarily, it may be well to state that conformity of type based upon clinical features is usually a matter of gradation, and that no attempt need be made to adhere to a rigid classification. Pneumonia of the aged differs from pneumonia in the aged in the following manner:

The disease is peculiar to the old and infirm, latent in its development, obscure in its manifestations, and erratic in its course. The familiar symptoms of pneumonia are absent or subdued, owing to mental and physical decline and debility and associated apathy of function and loss of sensibility and vigor. The constitutional symptoms are usually so slight as to cause no comment or complaint, and even when present early in the affection they are rarely sufficiently distinctive in character for one to decide whether they are due to grave disease or those ill-defined and transitory ailments of feeble old age. The attention is not at-

tracted or the diagnosis most difficult, and consequently the disease is frequently unperceived and death assigned to other causes. Experience with the affection is mostly limited to institutions for the aged. The autopsy occasionally reveals evidence of advanced pneumonia, previously unsuspected. It is often the cause of mysterious sudden death in the aged, and might be found many times where such causes are assigned as senile debility and cardiac disease. The literature contains very little mention of this common and very fatal form of pneumonia. In the climate of the Northern States pneumonia appears to be the cause of more deaths among the aged than all other diseases combined. Statistical information seems to show that the mortality rate in those over sixty years of age is about eighty per cent. and steadily increases with advancing age. Some authorities state that after sixty five years pneumonia is the cause of death in ninety per cent. These conclusions at least demonstrate the frequency of pneumonia in old people, and make the recognition of the most obscure and elusive cases important. In 1887 I published a rather complete clinical study of pneumonia of the aged, and endeavored to direct attention to the vague manifestations of this often perplexing affection. Since that time increasing experience has only strengthened the belief that it is frequently overlooked entirely, and that many who have not enjoyed special opportunities for investigation meet with unnecessary difficulty in determining its presence.

At this time the object will be to attract renewed attention to the subject, and to point out some of the chief clinical features to assist in diagnosis. It must be remarked that there is a vast difference between vigorous and feeble old age, and in the resistance which these conditions offer to disease. We are accustomed to classic descriptions of the indications of morbid conditions in the average human being of adult life, and perhaps too little stress is laid upon the influence of senility and its accompanying changes in structure and function. In debilitated old age the symptoms are less pronounced, and the value and character of physical signs often lose their significance. The inquiry must be directed, therefore, to the evidence of disease as modified by these changes, and their value estimated many times by another standard of health. We are chiefly concerned with the facts that pneumonia of the aged is atypical when compared with the description in the text books, that the difference in clinical manifestations is due to the causes already mentioned, and that a diagnosis depends upon an acquaintance with their relative value and meaning. The vast majority of all cases occur between November and May. In Buffalo the largest number develop in March, and seem to follow a cold northeast or east wind, whether the individual be confined to the house or not. The upper lobe is more often affected than in the middle-aged adult, and the disease more inclined to extend downward. In the stage of congestion the affected portion crepitates less, and the lung does not sink, as a rule, in water. The exudate is more fluid, and it is sometimes difficult to decide whether the lung is simply congested or beginning consolidation is present. Sometimes, owing to extreme rarefaction, the lung when hepatized does not sink to the bottom

<sup>\*</sup> Read before the Medical Society of the State of New York at its eighty-eighth annual meeting.

of the vessel. The left lung is involved nearly if not quite as often as the right.

The pneumonia is more often double, and ædema is much more common. Tubercular pneumonia is more com mon than is generally believed, and there is a similarity in the clinical features. Lobar pneumonia, due to mixed infection, often follows tubercular infiltration in the aged. The clinical history is marked by the absence of the usual symptoms, or their obscurity. There are cases where the patient does not betray the slightest indication of his condition. He may walk about as usual, partake of his meals, and suddenly die without any complaint or reference to illness. As a rule the symptoms are indefinite, and much care is required for their detection. Any disturbance does not cause so much uneasiness as in the middle aged, and subjective symptoms are not mentioned. The premonitory symptoms rarely attract any attention, and the invasion of the disease is often unrecognized, because the symptoms are vague and not of a nature to direct attention to the chest. At times, however, the onset is pronounced, and may be accompanied by delirium and great prostration. The initial chill is rarely well marked and is sometimes absent. The most constant and reliable symptom at the outset is the elevation of temperature, usually ranging from 102° to 103°. The temperature should be taken in the rectum, as the axillary and buccal temperatures show inaccuracies and fluctuations in the aged. Later the temperature may reach 104° to 105°, or even higher. The pulse, owing to the frequency of arterial changes, is unreliable; acceleration is the cause of suspicion, but trustworthy information can best be obtained by cardiac auscultation. The respirations are not relatively increased, as in adults. Sometimes they are of a puffing or panting character. Dyspnæa and catching respiration is not particularly noticeable unless the apex is affected. The respirations rarely pass twenty-five or thirty per minute. Any effort in breathing, combined with raising of the shoulder, should lead to an examination. Cough may be slight or wanting. The cough and dyspnæa of chronic bronchitis or asthma sometimes subside during an attack of pneumonia. The characteristic sputum is rarely present. It is oftenest thin, lacking in cell elements, and, when due to coexisting cedema, watery. My experience is in accord with the authorities who state that the expectoration never becomes purulent in the stage of resolution. The absence of pleurisy as a complication is most notable, and in the large proportion of cases there is no complaint of pain. The countenance affords valuable information in the way of expression and change of color, and the mental faculties are almost always perturbed in febrile disturbances of old age. The course and duration of the disease differ from those of middle life in that the completion of the earlier stages is sooner accomplished and the stage of resolution more protracted. Recovery, when it occurs, is generally marked by a somewhat lengthened crisis; and the critical diarrhea continuing through the lysis is more common than a critical sweat.

The inexperienced physician finds that physical examination of the chest of the aged is a new problem. Senile changes in the lungs and chest wall modify sounds, and

practice alone can make one familiar with their altered character. At first there is a tendency to arrive at erroneous conclusions, aside from the suspicions aroused by the slightly altered breathing, and physical signs offer little information until the exudate has filled a portion of the lung to a considerable extent; dullness is often a sign of relative value only. The crepitant râle is seldom heard. It may be developed occasionally by obliging the patient to take a deep inspiration, but as a rule the disease is not detected until too late. If the breathing is tubular anywhere it is apt to be heard over the root of the lung. Dullness over the upper lobe is not as marked as at the base, owing to the rigidity of the sternum and chest wall and the retraction of the lung away from the ribs. Tubular or bronchial breathing, when found, is most distinctive and sufficient for a diagnosis. It is even more intense than that heard in the adult, and is often more metallic in quality. Bronchophony is changed somewhat by the weak, quavering voice, and resembles ægophony. Deep percussion is more apt to bring out the resonance of the whole chest, and should be employed carefully. Areas of dullness found in the chest of the aged may be due to senile changes, and are often confusing. Fluid in the pleural cavity is often overlooked, and much may accumulate with slight disturbance. The insertion of a needle is more often necessary to arrive at a diagnosis. Cases occur in which the exploration of the chest gives negative or confusing results, and it becomes necessary at times to depend somewhat upon the associated symptoms; especially is this true in the earlier stages.

These briefly constitute the more reliable signs and symptoms. The important point in diagnosis is to suspect and search for trustworthy evidences of the disease. It is necessary to appreciate the extreme frequency of pneumonia in old people; the fact that of all acute diseases of the aged, pneumonia is oftenest latent, and that it produces the highest range of temperature and greatest prostration. The symptoms to be observed with greatest caution are the chill, brown, red, or dry tongue, malaise, change in breathing, malar flush, cyanosis, delirium, cough, slightest pain, prostration, increase in pulse beat, and finally the rectal temperature. The symptoms are confusing at first, and often point to cardiac and cerebral disease. It is a wise rule to exclude pneumonia of the aged, and not disregard the slightest deviation from the usual standard. Of all the characteristic symptoms, elevation of the rectal temperature is the most constant and important. I have never noted its absence, even in walking cases or in the insane. At times it is the only indication of acute disease in the aged. Broncho-pneumonia may not be associated with pyrexia, but my experience would indicate at least that lobar pneumonia of the aged is seldom afebrile in character.

The diagnosis must rest largely upon the high temperature and the physical signs. The diseases which frequently simulate pneumonia of the aged are hypostatic congestion, simple congestion, œdema, capillary bronchitis, pleurisy withor without effusion, and tubercular infiltration. The differentiation can not always be made by consulting the physical signs, but generally it is not difficult if prominent features

.

of the case are considered. The points of differential diagnosis are not so broadly defined in the aged, and analysis must be cautious and slow. Finally, pneumonia of the aged is often secondary or complicating, and many times hepatization is revealed at the autopsy as the direct cause of death. In these cases the disease is unsuspected because the attention is confined to another ailment.

## TECHNIQUE OF KIDNEY OPERATIONS.

By FRANCIS L. HAYNES, M. D.,

THREE important points in the surgery of the kidneys and ureters have recently been developed.

- 1. The kidney and the upper end of the ureter may be withdrawn from the abdominal cavity, both thoroughly explored, and returned to their position, without producing any serious results. Probably the best way to explore the kidney is to split it along its back, insert a finger into its pelvis, and apply the fingers of the other hand to the entire periphery of the kidney, thus making a complete bimanual examination. Any suspicious points may be cut into and inspected, taking care to make the incisions in the direction of the urinary tubules. The ureter may then be explored by a bougie. Cabot has shown that a good portion of the ureter may be exposed outside the peritonæum by an appropriate incision and by displacing the peritonæum in somewhat the same manner as for ligation of the internal iliac.
- 2. All hæmorrhage may be checked by catgut sutures, passed with a round needle in such a manner that neither the pelvis of the kidney, the ureter, nor the renal artery or vein shall be completely obstructed. Large wounds of the kidney or its pelvis may be very rapidly and efficiently closed and all hæmorrhage at once checked by passing a long, slender, round needle, threaded with catgut (not chromicized), entirely through the kidney at the site of the lesion; then inserting the needle at a distance of from a quarter to two inches from the point from which it had just been withdrawn, passing it again entirely through the kidney; the thread is then to be tied with just sufficient firmness to bring the surfaces of the wound in apposition and check the hæmorrhage. Any number of these mattress sutures necessary to produce the desired effect may be used, and they may be supplemented by any other variety of suture, always using catgut.
- 3. Ureteral anastomosis, as devised by Weller van Hook, of Chicago, and practiced successfully by Howard Kelly, of Baltimore (in a woman whose ureter had just been divided during an operation for fibroma), is also destined to play an important part in surgery. My friend Dr. Penrose, of Philadelphia, has made a further advance. While doing an abdominal hysterectomy he deliberately excised the lower portion of a ureter involved in the malignant growth and, after ligating the bladder end of the ureter, transplanted the kidney end into the bladder and closed the abdominal wound without drainage; the patient made an uneventful recovery.

I say nothing of excision of portions of the kidney, as

this procedure is still in its infancy. Doubtless it will soon become a well-established operation.

The first procedure described was conceived by three men independently. It was first published by myself, in the Southern California Practitioner, September, 1893. The first operation done by me was on Robert Relstab, December 10, 1892 (nephro-lithotomy). The procedure was next described by Noble (N. Y. Med. Jour., March 3, 1894). His operation was done on December 12, 1893. Dr. Noble was evidently ignorant of my note; and when I did my operation I did not know that my friend Dr. Howard Kelly had anticipated me. I have recently received a letter from him in which he informs me that he had done the same operation in May, 1892 (several months before my operation).

929 SOUTH MAIN STREET.

## PNEUMONIA-GANGRENE.

By E. A. REILLY, M. D.,

On the 20th of March, 1892, I was called to see Miss S., aged fifteen years. Upon arriving at her home her mother, whose face wore a troubled and anxious look, informed me that she feared her daughter, for the first time in her life, was a very sick girl; that two or three days previous to my visit Miss S, had attended a social gathering in their immediate neighborhood which resulted in her contracting a severe cold. All the known domestic remedies had been exhausted without success. The patient grew steadily worse until the morning of the 20th, when she suffered a severe chill, and complained of a pain in the right side. The patient had always been a strong and vigorous girl, yet when I saw her, six hours after her chill, she was greatly prostrated, with a dull, heavy expression. Her face was flushed, hot, and dry. Respiration was greatly accelerated, being shallow and irregular, which rendered her speech difficult and broken. She had a short, backing cough, attended with a labored expectoration of tenacious and rusty sputa. Her pulse was small and reached 112 pulsations a minute. Her temperature was 104.3°. There was great thirst and the tongue was dry and forred. The pain in her side was very acute and constant; its presence caused the patient great anxiety and distress, it being aggravated every time she coughed or took a deep breath. After making an examination of the chest I found in the middle and lower lobes of the right lung slight dullness on percussion, and on putting the ear to the chest wall in this locality I found a succession of fine, dry, crackling sounds, disclosing the characteristic crepitant râles of pneumonia. It not being my intention in reporting this case to offer anything new in the care or treatment of pneumonia, but more particularly to call your attention to its very unique termination or complication, permit me to say that Miss S. endured a regular ten days' run of pneumonia, passing the crisis with no relapses or apparent complications, and terminating in complete resolution.

On March 31st the patient was able to sit erect in the bed, to eat and sleep well, seeming in spirit and feeling as well and happy as ever. My visits ceased two days after, and I heard no more of the patient until April 15th, when I was again called to see her. Her mother explained that two or three days after I left the patient seemed to fail. Her appetite left, her bow-

<sup>\*</sup> Read before the Elmira Academy of Medicine, February 7, 1894.

els were constipated, her usual cheerfulness had succumbed to a feeling of lassitude and indifference, until she had again taken to her bed, and had remained there for the previous two days. I made a very careful examination of her chest but found no symptoms of disease in the organs of respiration and circulation; her pulse was small and weak, about 82 a minute. Temperature normal. Her mother informed me that there had been no operation of the bowels in three days, and that the menstrual period was delayed six weeks. Upon asking the patient how she felt, she answered that she did not know, that her feelings were so strange and queer she could not explain them. To quote her own language, she said: "I have neither pains nor aches, neither courage nor fear. I do not want to get up, neither do I want to remain in bed. I can not sleep or eat, I can not think. Oh, dear! I do not know how I feel." I ordered a cathartic and left a sleeping potion, promising to return next day. On the next day, April 16th, I found that she had slept well during the night and in the early morning the bowels moved thoroughly. She seemed slightly improved, and I ordered a tonic of iron, strychnine, and quinine. After an interval of two days I visited her again. At this time her mother called my attention to a swelling and soreness of the outer margin of the right ear, extending down into the lobule. Believing that it was perhaps due to the fact that she rested mostly on that side, I dismissed it as trivial. She seemed no better; on the contrary, she seemed weaker and more restless. On the following morning I was hastily summoned, and found the patient suffering such violent pains in both legs and thighs that her cries alarmed the neighborhood. I gave a hypodermic of morphine, which was repeated again in the evening. The next morning complaint was made of pain in the toes, the margin of both ears, also in the shoulders and arms, extending to the finger tips. In the course of forty-eight hours the toes and fingers became much swollen, also the tip of the nose and superior margins of both ears. The hands and feet, also both cheeks to a less degree, were covered with spots of purpura, which rapidly became black, shriveled up, and fell off, indicating that the skin only had been attacked. This was also the result with the tip of the nose and the margins of the ears. The process was different with the toes and fingers. They were swollen and very painful, of a bluish-red color in some parts, of a dark livid in others, all being icy cold. Shortly after this, small seropurulent vesicles appeared, destroying the skin and laying the parts bare. It appeared now that the parts were to be restored, but after a time, when the diseased members were nearly healed, the attack again returned. This was repeated in a space of three weeks four or five consecutive times. All the fingers recovered; but in the case of the second and third toes of each foot it was of longer duration, and there followed from the consecutive hyperæmia a true mummification or dry gangrene, which terminated with a falling off of the last phalanx of the four toes The treatment all through the six weeks was of a quieting and supporting sort. There was no elevation of temperature and but slight increase in the pulse rate. At the time of the falling off of the toes the patient was gaining in strength and flesh rapidly. In two months she walked with no appreciable difficulty. She has not been ill since and is enjoying perfect health.

We are told that recovery from this form of gangrene is rare. I have never seen or heard of a case of this kind before. I can find no literature upon the subject. The books tell us that gangrene may occur in the course of certain severe diseases, such as diabetes, typhus, typhoid, measles, scarlet fever, and diphtheria, but no reference is made to

this form ever following a typical case of acute pneumonia. There is a form of gangrene referred to by the older writers called "ergotism," which seems to have passed away from modern observation, and in view of the very free use of ergot at the present time without the results heretofore described, there may be a serious doubt as to whether the disease was not largely due to the straitened and impoverished condition of the patients who had taken or used the ergotized rye and wheat. It was looked upon in the middle ages as a miraculous punishment from the hand of the Deity. The first accurate account of this affection dates back to 1597. In 1747 a fatal epidemic of this kind raged in southern Europe, where rye bread was extensively used. Many who were too poor to buy the rye made their bread from the refuse after sifting. A French writer tells of a man and wife and two children who perished miserably after eating bread of this kind. The third, an infant at the breast, who had eaten panada made with this flour, escaped death, but was deprived of both feet by gangrene.

In searching the writings of the various authors I learned that the majority arranged the varieties as moist gangrene, dry gangrene, senile gangrene, white gangrene, symmetrical gangrene, diabetic gangrene, diphtheritic gangrene, noma, and hospital gangrene. Under none of these heads can I securely fit my case. The nearest approach to it is in a description by Raynaud, in 1862, of what he calls relapsing gangrene. His was the first accurate description. He describes it as attacking the fingers, toes, tip of the nose, and external ears. He says it is exceedingly rare, Billroth, up to 1872, having met with a single case, and other observers with extensive experience having seen no example.

According to Raynaud, the disease occurs chiefly in chlorotic and nervous individuals of early adult life, patients in convalescence from typhoid fever and similar exhausting diseases. You will observe that my patient, on the contrary, was not chlorotic or nervous. Raynaud further states in his description that four months beforehand the affected part suddenly becomes white, bloodless, without feeling—dead. The skin is strongly wrinkled and shrunken, the ends of the fingers appear thin and conical. You will observe in Miss S.'s case the onset was rapid and severe and the affected parts swollen and hyperæmic. In closing his remarks Raynaud states that the falling off of the last phalanx is the usual termination of these cases, which point of fact agrees with the fate of the four toes in Miss S.'s case.

This is all I have been able to find upon the subject. Dr. W. C. Wey, Dr. H. D. Wey, and Dr. T. A. Dundas saw the case before separation took place, and pronounced it very interesting and unique, all of which prompted me for further information to place it before the Academy of Medicine for discussion.

cinnati.

## LITHLEMIA:

ITS RELATION TO THE GOUTY STATE; ITS COMPLICATIONS AND TREATMENT.

By JOHN V. SHOEMAKER, A. W., M. D., PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND CLINICAL PROFESSOR OF SKIN AND TENERAL DISSASSIN, IN THE MEDICO-CHIRCHOCAL COLEGE OF PHILADELPHIA, ETC.

During the past year my attention has been especially attracted to the number of cases which I have seen, both in private and hospital practice, of patients presenting, as Fothergill would say, "the protean manifestations of gout," but which we are now accustomed to group under the comprehensive title of "lithæmia," for our knowledge of which we are especially indebted to Murchison and Da Costa. It has occurred to me that the financial panic and prevailing depression in business circles has increased the anxieties and causes of nervous strain among the people to such an extent as to seriously affect the health of the community. At all events, if moral and emotional causes may precipitate an attack of acute gout, which is generally believed to be the case, then it is not altogether beyond the bounds of probability that depressing and annoying circumstances, with accompanying disturbance of digestion, might in a strictly analogous way produce the condition of lithæmia. This view is rendered more probable since Professor Da Costa has recently stated it as his conviction that the latter is the form which gout principally assumes in the United States; in fact, he calls lithæmia "American gout."

As some of the cases which I have seen recently have presented symptoms, such as neuralgic or myalgic pains, skin eruptions, and digestive disorders, the gouty origin of which was not previously suspected, but which was demonstrated by the treatment, I have thought it well to make a brief record of a few of them, principally to illustrate the method of treatment and to report its results.

Before quoting any clinical histories, however, it may be as well to briefly review the modern doctrine of the pathology of the gouty state. By doing this it is possible that its relation to lithæmia and its complications, and also the rationale of the treatment, may be more clearly understood. Although gout was very well known to the ancients from the clinical point of view, its actual nature was entirely unknown until Garrod announced his discovery of the excess of uric acid in the blood. He showed that in chronic gout the blood, even in the intervals between the exacerbations, was always rich in uric acid; while in the acute attack, even when the urine shows a deficiency of uric acid, "it exists in the blood in abnormal quantities."

Sir William Roberts has further shown that in gouty persons and conditions there is a tendency to the formation of urates which are less soluble than the normal form, and that, therefore, a precipitation is liable to occur in favorable locations, such as in the neighborhood of joints and in the auricles. The following is a brief abstract of his views on the chemistry of uric acid, gravel, and gout, as expressed in the Croonian Lectures delivered last year before the Royal College of Physicians of London. With Garrod, A. Haig, and others, he regards the accumulation of the biurate of sodium and its deposit in various tissues

as the most characteristic feature of gout. "The arthritic incidents of gout may be said, not improperly, to be simply incidents pertaining to the precipitation of these crystals in the structures of the joints." He further declares that "were it possible for us to keep the sodium biurate in a state of solution in the bodily fluids, the clinical portraiture of gout would be completely transfigured." Fortunately, it appears that in Buffalo lithia water Nature has provided us with an agent the action of which is mainly to accomplish the solution of the sodium biurate and to carry it off, with other principles of waste, through the ordinary channels of excretion, out of the body. Its modus operandi being comprehended, it is evident that the clinical portraiture of gout may be transfigured by the use of just such a simple agent, which, by the way, has the rare advantage of being free from toxic or injurious qualities.

Some of the details of the investigations made by Sir William Roberts possess considerable therapeutic interest. Thus, he carefully determined the solubility of sodium biurate in water, blood serum, synovia, and in other fluids, and found it very sparingly soluble; in fact, not more than one part in ten thousand of these fluids. Experiments were next made to test the solubility of sodium biurate in various saline solutions, particularly those of sodium, potassium, calcium, magnesium, and ammonium. Instead of increasing the solvent power of the menstruum kept at the temperature of the human body, the addition of any of these salts lessened such solvent power to a marked degree, except those of potassium, which appeared to exert no influence. It was further ascertained that the influence of the salts depended entirely upon the nature of the base and not on their acid or alkaline reaction. By another series of experiments the same observer appears to have succeeded in showing that when uric acid is added to blood serum, or synovia, at the temperature of the body, it enters into combination with the sodium carbonate, forming first a quadrurate, but subsequently it takes another atom of the base and becomes a biurate of less solubility, and hence precipitates in the crystalline form. These changes are supposed to represent what actually takes place in an attack of gout. While the quantity of uric acid in the blood and synovial fluids remains small, it is held in solution and eliminated as a quadrurate, but when the proportion becomes excessive, it changes to a biurate and soon precipitates, bringing with it the active phenomena of

There is entire agreement among authorities as to the clinical symptoms and the immediate underlying conditions of the gouty state, but as regards the efficient cause of the excessive formation of uric acid and abnormal urates there is still a lack of agreement among the pathologists. Fothergill thought that it was due to the liver, and explained it quite ingeniously on the ground of comparative physiology. His assertion was that "gout is hepatic reversion—the formation of primitive urine products by a mammalian liver." Vindevogel, in a monograph upon the

<sup>\*</sup> Annual of the Universal Medical Sciences, 1893, vol. i, section K, p. 7.

Nature. Causes, and Conditions of Gout,\* alleges as an essential part of the pathology of gout an enfeeblement or lessened activity of the trophic nervous centers and a loss of equilibrium between the processes of assimilation and disassimilation, by which the products of disintegration are rendered incomplete or toxic to the economy.

Quite recently Professor Da Costa, in discussing the subject of lithæmia, + states that there may be other excrementitious or pathogenic principles at fault besides uric acid, and strongly objects to narrowing the consideration to a single chemical substance. He believes that this is taking entirely too restricted a view of the condition. For him lithæmia is a morbid state in which the income of nutrition is in excess of the outgo of waste. The quantity of food is greater than either the needs of the system require or the organs of excretion can properly dispose of. There is defective oxidation as well as deficient elimination. The consequence of the excessive ingestion of food is that the functions of the liver are imperfectly performed, and there is generally more or less hepatic disorder. The blood contains urates in excess and frequently oxalates, also other imperfectly elaborated products of waste; possibly it may be yet further poisoned by ptomaines resulting from imperfect gastric and intestinal indigestion.

It seems evident, therefore, that while a great difference of opinion exists as to the ultimate cause of gout, whether it be of nerve or blood origin or due to failure of liver, kidneys, or the digestive organs, all authorities are in accord upon one thing, and that is that the condition to which our therapeutic efforts must be directed in order to relieve the patient is an excess of uric acid and other waste products in the blood. It is to this condition that the symptoms and sequelæ are now generally attributed.

It is quite probable that there may also be a failure of the glands of the skin to properly perform their functions, as has been asserted by some observers. At all events, it can easily be shown that certain forms of eruption upon the general surface are of a gouty nature and are curable by applying the treatment suitable for the underlying gouty condition. Among the notes of cases that are referred to in this paper one or two will be found which furnish a good illustration of this fact.

Having thus hastily reviewed the pathology of the gouty state, and indicated the conditions required to be fulfilled by the therapeutic method in order to remove this condition, I will now proceed to briefly narrate the history of a few cases which illustrate the benefit of such treatment.

Case I. Dyspepsia accompanying Lithamia.—Miss L., single, aged twenty years, applied to me for treatment for acid dyspepsia, with flatulent cructations, heartburn, and frequent headache. Examination of the urine, which was rather scanty, high-colored, acid, specific gravity 1.024, showed a deposit of urates and oxalates, and gave a clew to the cause of the dyspeptic symptoms. She was directed to avoid articles of food containing sugar or glucose, to eat meat sparingly, and to take freshair exercise each morning. Her medical treatment consisted of

half a glassful (f $\frac{\pi}{2}$ iv) of Buffalo lithia water three or four times a day. This afforded prompt relief, and the symptoms all disappeared in the course of a few days.

Case II. Chronic Gout.—Mrs. W., aged thirty-three years, a victim of inherited gout, complained of muscular pains and neuralgia in different parts of the body. Her digestion was poor, and she was inclined to acidity of the stomach. The same treatment as in the preceding case afforded prompt relief.

Case III. General Muscular Rheumatism of Lithæmic Origin.—George R., aged eighteen years, a clerk in a store, complained of pains in different parts of his body with tenderness in the muscles of his back and in the calves of his legs and shoulders. He had no fever. All muscular labor was irksome, and he complained of being constantly tired. He was ordered four ounces of Buffalo lithia water four times a day and good diet. The result was complete recovery in less than a week.

Case IV. Subacute Gout in the Fingers and Toes.—Mr. R. S., aged fifty-three years, a merchant, presented himself with gouty deposits around the small joints of his fingers and toes. In the affected articulations there was also impairment of motion and a moderate degree of inflammation, with pain and tenderness. There was no fever. He had never had an acute paroxysm of gout, although of gouty family. He was ordered an aperient now and then, with a restricted diet and Buffalo lithia water, the latter in five-ounce quantities four times a day. This was followed by the disappearance of all the symptoms of gout, at least for the present.

Case V. Periodic Attacks of Gravel.—Julius R., fifty-two years of age, a commercial traveler, complained of passing gravel; with this there was lumbar pain and a slight increase in temperature. The urine contained crystals of uric acid with urates and a small amount of albumin. No casts were detected. He had been subject to similar attacks for four or five years, coming on at times, probably connected with irregularities in eating. He was given two ounces, afterward increased to four, of Buffalo lithia water every two hours, with ordinary attention to his diet. This gave immediate relief and was followed by recovery.

Case VI. Gastric Catarrh.—Mr. R. P., aged forty years, a bookkeeper, of somewhat irregular habits, presented the ordinary symptoms of mild gastritis, or what is often termed gastric catarrh. After a preliminary dose of calomel and soda, he was ordered to take Buffalo lithia water as his sole drink, using about two pints daily. His diet was restricted to light articles of food, which did not require gastric digestion. As his general condition seemed good no other medication was considered necessary. Rest in bed for two days was advised, followed by moderate exercise. The lithia water was subsequently reduced to four ounces four times a day, and the patient reported himself as perfectly recovered at the end of a week.

Case VII. Acute Rheumatism in a Lithamic Patient.—Fannie S., aged thirteen years, a school-girl. This patient was in bed with swollen knee and ankle joints, fever, and, in fact the usual clinical appearances of acute rheumatism. As there was a gouty tendency in the parents, I gave her the lithia water in two-ounce doses every two hours, the interval increased to three hours as the symptoms subsided. This was followed by relief from all the symptoms, with free action of the skin and kidneys, and in the course of the first week she entered an easy and rapid convalescence.

CASE VIII. General Articular Rheumatism.—William B., aged seventeen years, working in a dry-goods store, and who had been exposed to cold and wet, had an attack of articular rheumatism especially affecting the knees and ankles. He was given three or four ounces of Buffalo lithia water every four hours, with hot drinks to increase the action upon the skin.

<sup>\*</sup> Brussels, 1892.

<sup>+</sup> Editorial, Medical News, March 17, 1894.

The case gradually improved and made a good recovery. No salicylates or coal-tar preparations were employed in this case. He made a good recovery without any complication.

Case IX. Confirmed Gout .- Mrs. Q., aged sixty years, complained of pain and tenderness in her fingers and toes, which were much deformed by gouty deposits. In this case the large joints were also stiff and painful on motion. Her general nutrition was poor, and she had some cardiac hypertrophy with increased arterial tension. The arteries showed atheromatous thickening and there was a systolic murmur indicating aortic valvular disease, but without marked stenosis. She was ordered a suitable diet and recommended to change her residence to a more appropriate climate, where she could spend much of her time in the fresh air. In the meantime she was to take four to five ounces of Buffalo lithia water from five to six times a day. The latter treatment was attended with the best results; the pain disappeared from the joints and the swelling around them was materially lessened. She felt so much better that she could not be induced to take the other part of the prescription which called for a change of climate, since she found herself so much benefited by the water that she did not consider it necessary to leave home.

Case X. tiont of the Feet with Eczema.—Mr. R. B., aged forty-nine years, has chronic gout in the feet, with deformity which interferes to some extent with walking. He also presented an eczematous cruption around the flexures of the thighs and on both arms. He was ordered from one to two pints of Buffalo lithia water daily. His diet was restricted and a mild aperient given, to be used three or four times a week, or every day if found necessary. As much exercise in the open air as could be taken was insisted upon, which was not much at first but soon increased, so that he spent most of his time out of doors. This treatment enabled him to overcome the gout, and to get rid of the eczema as well, in the course of three months.

Case XI. Gouty Dyspepsia.—William F., aged thirty-six years, had gouty deposits in the fingers on both hands. At present he is suffering with acid dyspepsia, for which he had used ordinary remedies without relief. He was ordered to take one ordinary glassful of hot Buffalo lithia water on rising each morning. About half the quantity, also hot, he was directed to take before his dinner and supper, and again a full glass at bedtime. Under a few days of this treatment the dyspepsia entirely disappeared and the swelling in the hands was very much ameliorated.

Case XII. Lithemic Diabetes and Eczema.—Lizzie C., aged forty-four years, had an eczematous eruption of a chronic character upon different parts of her body. She also had acidity of the stomach. Examination of her urine revealed the presence of a considerable proportion of sugar. Her diet was carefully regulated, and she was directed to live principally upon the green vegetables, poultry, and fish. Fresh-air exercise was also insisted upon as an important part of the treatment. Three or four ordinary glassfuls of Buffalo lithia water were directed to be taken every day. Under this simple treatment all the symptoms were alleviated and she steadily improved. When her stomach was in a condition to bear it, she was given ergot and iron, and the disease has been thus kept in abevance.

Case XIII. Psoriasis with Rheumatic Symptoms.—Mr. R. W., aged twenty-nine years, had general psoriasis, distributed over the surface of his body and extremities. The disease had developed gradually since its first appearance more than a year before. He also was subject to attacks of what he called rheumatism, every now and then, probably connected with errors in diet. Under the use of Buffalo lithia water, a glassful four

to six times daily, the symptoms slowly but surely yielded; ten grains of salicin were subsequently added to each dose of the water. When I last saw this patient he was in good general health, without any rheumatism or indigestion, and the psoriasis had faded so as to be scarcely visible.

Case XIV. General Eczema with Acid Dyspepsia.—Mr. W. A., aged thirty-four years. This patient had eczema of his entire body. He also had acidity of the stomach and an acid urine, and attacks of pain in the bowels of a colicky character. His diet was regulated and he was directed to take exercise in the open air. His medical treatment consisted solely of Buffalo lithia water as in most of the preceding cases, four or five ounces several times a day. The result was a speedy recovery.

# SIMULTANEOUS DISLOCATION OF BOTH SHOULDERS.

BY CHARLES A. POWERS, M. D.

This injury is not of frequent occurrence. On this account, and because of the distinct manner in which the accident occurred, brief narration is made of the following:

Case.—On December 21, 1893, I was asked by Dr. Geoffrey R. Bourke to see Mrs. M., a stout woman of sixty-five years, who had sustained an accident three weeks previously.

On December 1st, while walking from one room to another, she had tripped on a piece of carpeting, falling forcibly forward, both arms being raised above her head and the weight of the body being received on both outstretched forearms and clows. There was some shock, for which she had been treated by a neighboring physician. She had remained in bed, unable to use the arms. When examined by me both shoulders were found to be dislocated, the left beneath the coracoid process, the right into the axilla.

Under ether the moderately firm adhesions were gradually broken up by gentle manipulations, the right shoulder going back at the end of fifteen minutes, the left in about five minutes.

Double sling and body bandage for four weeks. The patient suffers with chronic rheumatism; the functions have been slow in returning, and are not yet complete.

## OPERATION AND AFTER-TREATMENT FOR NON-MALIGNANT STRICTURE OF THE RECTUM.

By J. L. MEDINA, M. D.,

EX-HOUSE SURGEON OF THE FRENCH HOSPITAL;
ATTENDING SURGEON TO THE FRENCH HOSPITAL'S DISPENSARY;
ATTENDING PHYSICIAN TO THE NORTHWESTERN DISPESSARY.

WHENEVER an operation for the cure of non-malignant stricture of the rectum is described, most of our text-books and standard works recommend as the best "Verneuil's" operation. This consists in the division of the stricture in the posterior median line by a single incision. The after-treatment consists in the use of rectal bougies passed at intervals, usually beginning a few days after the operation.

I will relate now the history of a case that I operated lately, following an entirely different plan, obtaining the most successful results:

Miss L. H., thirty years of age, single, has suffered for the last three years with continuous muco-purulent discharges from the rectum. The act of defecation was very difficult and generally accompanied by most distressing pain. Had dysentery some years ago. There was no specific history.

I saw the case in consultation first, and, upon examination, I found a circular stricture, beginning two inches and a half from the anus, extending upward for an inch and a half. The lumen of the rectum at the seat of the stricture was only about a third of an inch in diameter. There was considerable ulceration above the stricture produced by the constant accumulation of fæces. The diagnosis of non-malignant stricture was made, and I advised an operation as the quickest permanent cure.

Later on I was requested by her physician to operate upon her. She was admitted into the French Hospital on the 5th of March, and prepared for operation the next day.

Operation.—The patient, being under ether, was placed in Sims's position. The anus was dilated, and then I passed into the rectum a small Sims's vaginal speculum, using the blade toward the anterior rectal wall, protecting in this manner the posterior vaginal wall from any possible injury. None of the many different rectal speculæ will give a more ample field to work upon than this.

Now I performed proctotomy in the posterior median line, but not by a single incision, as has been recommended, but by a double one, a quarter of an inch apart and meeting in the median line, removing a V-shaped piece through the whole length and thickness of the stricture. Dilatation was now performed without any resistance. During the operation one of the little branches of the middle hæmorrhoidal artery was severed, but the hæmorrhage was stopped at once by torsion.

The practice of beginning to pass bougies a few days after the linear division of the stricture seems to me to be the cause of many unsuccessful operations of this kind, as, in all probability, by that time the incision is united again, leaving the stricture in the original condition. Such being the case, bougies will not do more benefit than they did before an operation was undertaken. To avoid this I left in the rectum one of Sims's vaginal plugs, an inch in diameter by three inches and a half in length.

I removed the plug twenty-four hours after the operation, and treated the wound and ulcerated surface antiseptically with a solution of creolin, blowing in some iodoform, and replaced the plug. This was repeated every day.

The only objection I found in using Sims's vaginal plug for this purpose was that it keeps the anus dilated as much as the stricture, and has no opening for the escape of gases. To meet this defect I have designed a rectal plug. This is made of glass, hollow, with a constriction at the base, so that the anus will remain unstretched; then a straight portion, its length according to the length of the stricture. The end is slightly pointed and with several small holes for the exit of discharges.

The patient never had any pain or rise of temperature. She shert from the first night with the plug in without any discomfort at all. During the day she removed it, and replaced it herself only when about to have a passage.

She left the hospital seven days after the operation and went home, where I treated her in the same way, with the only addition of passing a larger plug (an inch and an eighth in diameter) for an hour three times a day.

At the end of the second week I sent her back to her own physician, as we had agreed. Lately I was informed by him that not a trace remains of the stricture, that all the cicatricial tissue had disappeared, declaring that the operation, at which he was present, had been a complete success.

I think that such a satisfactory result was due only to the V-shaped incision and to the constant dilatation from the time of the operation without waiting a few days, as has been the practice.

THE

# NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co. Edited by FRANK P. FOSTER, M. D

NEW YORK, SATURDAY, JUNE 2, 1894.

THE EDIBLE MUSHROOMS OF THE UNITED STATES.

THERE has recently been issued from the Government Printing Office an important pamphlet entitled Twelve Edible Mushrooms of the United States, with Directions for their Identification and their Preparation as Food, by Dr. Thomas Taylor, chief of the Division of Microscopy of the Department of Agriculture. The importance of the subject need not be insisted upon to the few who know how immensely superior the fresh American mushrooms are to those imported from Europe-as Mr. William Falconer, of Glen Cove, N. Y., puts it, in a summary contained in Dr. Taylor's pamphlet of a paper read before the Massachusetts Horticultural Society for February, "Many persons who have used the tasteless, indigestible, putty-balls from imported cans will repudiate the foreign article and accept no other than the wholesome, toothsome, and juicy domestic product." In this statement Mr. Falconer has reference to the time when, as he foresees, the production will have been so increased as to reduce the price from a fictitious to a popular basis. Dr. Taylor describes the following species: Lactarius deliciosus, Cantharellus cibarius, Marasmius oreades, Hydnum repandum, Agaricus campestris, Coprinus comatus, Morchella esculenta, Clavaria cinerea, Clavaria rugosa, Boletus edulis, Lycoperdon giganteum, and Fistulina hepatica. All these species are shown in colored lithographs and described sufficiently for their identification in the text, in which, moreover, directions are given for gathering, preserving, and cooking each one. In an appendix the reader is instructed how to cultivate mushrooms, and Mr. Falconer's description of a new species, Agaricus subrufescens, is quoted.

Dr. W. P. Gibbons, of Alameda, Cal., the chairman of the committee on indigenous botany, materia medica, pharmacy, and medical chemistry of the Medical Society of the State of California, read at the recent meeting of that society-for the advanced proofs of the report of which we are indebted to the Occidental Medical Times-a paper entitled Some of the Poisonous Plants of the Pacific Coast. In that paper he showed that our American mushrooms were much neglected as an article of food and as a substitute for meat, owing to their bad reputation among those who were unable to discriminate between the edible and the noxious species. While, he said, there was no doubt that sickness and death had resulted from eating certain varieties, among the most poisonous of which he classed the Amanita muscarius, formerly used as a fly poison, such accidents were to be attributed as a general thing to gathering the mushrooms at an unseasonable time and to neglect of the proper precautions in preparing them for the table rather than to any fixed poisonous principle in the plant. Even the Amanita muscarius, he said, was eaten by the Russian peasants after they had prepared it with salt and vinegar. It appears, however, that it is not enough to be able to discriminate between the different varieties of fungi, for mushrooms that are in themselves innocuous are apt to be attacked by flies and other insects which impart poisonous properties to them. Dr. Gibbons showed a small bottle containing minute coleopterous insects and another containing myriads of their larvæ, not distinguishable by the unassisted eye from fine dust. These had been taken from a specimen of Polyporus. He concluded by stating that there was no general rule by which edible mushrooms could be distinguished from noxious ones; in all cases they should be well treated with salt and vinegar before being cooked.

## THE MANAGEMENT OF SYPHILITIC MARRIED WOMEN,

M. Alfred Fournier, whose high attainments as a syphilologist are matched by his insight into human nature and by the purity of his ethical instincts, who, moreover, is well known to have made a special study of venereal diseases in their relation to the married state, lately devoted a lecture to the consideration of the physician's duty when a married woman seeks his advice for a trouble which he ascertains to be syphilis. The substance of M. Fournier's lecture is published in the Gazette de gynécologie, in the form of a feuilleton. The question is, when under such circumstances the woman asks to be informed as to the nature of her disease, What is the physician to do? If he tells her point blank, supposing her to be a virtuous wife, the husband is at once involved in the unenviable situation of having married while yet the subject of communicable syphilis or else accused of having subsequently contracted the disease by illicit intercourse. In either case the prospect is that of domestic discord and scandal, to say nothing of the unpleasant consequences to the physician himself, such as the husband's reproaches at the breach of secrecy. If, on the other hand, the wife has been infected by a paramour and remains ignorant of the nature of her disease, she is almost sure to give it to her husband. The question then is complicated and the situation delicate.

M. Fournier is of the opinion that whenever the physician is satisfied that a safeguard can be thrown around his patient only by his keeping silence, he is warranted in doing so, and in the case of a wife the prerogative rises to the level of a professional duty. But when the woman is of loose morality, such reticence may become dangerous; such a patient should be warned that she is tainted with a contagious disease, and told that it is incumbent on her to guard sedulously against spreading it. In a general way and to his own satisfaction for ordinary purposes, one may have no hesitation in concluding whether his patient is virtuous or not, but in such a grave situation what is wanted is to settle upon a course of procedure that leaves nothing to surmise. The best way is to suggest to the woman that her husband's co-operation in the necessary medication, etc., is desirable; if she assents, she is innocent, but, if she raises objections, she is culpable. In any event, however, the

physician should not confer with the husband without the wife's consent. It is true that to suggest such a conference may be to arouse suspicions and precipitate consequences that it is desirable to avoid, but, on the whole, this course is the least objectionable.

THE ANOMALIES AND COMPLICATIONS OF CHICKEN-POX.

In the Revue internationale de bibliographie médicale, pharmaceutique et vétérinaire for April 25th there is a summary of an article on this subject by Dr. L. Galliard, published in La Médecine moderne for January 13, 1894. The author maintains that in certain cases chicken-pox may be a serious disease, capricious in its course and difficult of diagnosis. The characteristic eruption of vesicles may in a few cases-there are twelve on record—be preceded, accompanied, or followed by a rash, which is usually like that of scarlet fever, commonly lasts for twenty-four hours, and is accompanied by fever, but is apparently destitute of any prognostic significance. The varicellous vesicles may be very few, most of the lesions being arrested in the papular stage. This is the papular form of varicella. They may be very confluent or attain extraordinary dimensions (bullous or pemphigoid varicella), or become pustular (globo-pustular varicella). The exanthem is not restricted to the skin, but invades the mucous membranes also.

The author reports a case in which varicellous angina and stomatitis were so intense as to cause the patient great suffering and impress upon the disease a seal of gravity well worthy of attention. This case was characterized, moreover, by the absence of vesicles on the integument and by the purely papular formation of the cutaneous exanthem. In several instances hæmorrhages have been noticed in chicken-pox. Bleeding from the nose is frequent; the other homorrhages are exceptional. As to true hæmorrhagic varicella, it is a clinical rarity. Henoch and subsequent observers are mentioned as having described a varicellous nephritis which, although generally benign, may be a grave complication and even lead to death, Therefore the urine should be examined in all cases. Pseudorheumatism is a very exceptional complication; only two cases are known. Gangrene is the most formidable of the complications of chicken-pox, and it is the one that has longest been known. At the outset of the disease there is nothing to show that this complication is about to occur; it makes its appearance in cases that are apparently the simplest. The gangrene generally shows itself at the margin of the vesicles, which ulcerate, and the mortification proceeds from one to another. Death is the usual result, but recovery has been observed. A case of gangrene of the limbs in consequence of arterial obstruction has been cited by Bellamy. Among the other possible complications of varicella mentioned by Galliard are furuncles, abscesses, and erysipelas.

THE INFLUENCE OF OOPHORECTOMY ON THE VOICE.

cation, etc., is desirable; if she assents, she is innocent, but, if she

According to an account given in the Progrès médical for
raises objections, she is culpable. In any event, however, the

May 5th, Dr. Moure, of Bordeaux, stated at a recent meeting of

the Societé française d'otologie that in two women who had undergone this operation he had observed that the voice had become strong and coarse. One of them, who had originally had a soprano voice, had lost her high notes and almost become a contralto. The laryngoscopical examination had not shown any anomaly of the vocal organs. Dr. Moure asked if such disturbances of the voice might not be attributed to elongation of the vocal bands or to a more considerable development of the threeoid cartilage.

#### MIGRAININE.

OVERLACH (Disch. med. Woch., 1893, No. 47; Rev. internat. de bibliog., etc., Apr. 10, 1894) has given this name to a mixture (in unmentioned proportions) of antipyrine, citric acid, and caffeine. The ordinary dose for twenty-four hours is said to be about seventeen grains, which may be increased to forty grains. It is alleged not only that it cuts short the attacks of migraine, but that it lessens their frequency. It is reported to have been found useful also in headache due to influenza, alcohol, tobacco, and morphine.

### ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending May 29, 1894:

DISEASES.	Week ending May 22. Week ending May 29,			
	Санев.	Deaths.	Cases.	Deaths.
Typhoid fever	6	1	5	8
Searlet fever	136	10	136	17
Cerebro-spinal meningitis	. 4	3	3	1
Measles	. 162	10	146	5
Diphtheria	237	67	258	67
Small-pox	11	6	55	3

Change of Address.—Dr. George C. S. Choate, to No. 85 Madison Avenue.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 20 to May 26, 1894:

Ball, Robert B., Captain and Assistant Surgeon, is relieved from temporary duty at Fort Monroe, Virginia, and ordered to Fort Adams, Rhode Island, for duty, relieving Borden, William C., Captain and Assistant Surgeon. Captain Borden, on being thus relieved, is ordered to Fort Snelling, Minnesota, for duty at that post, relieving Mason, Charles F., Captain and Assistant Surgeon. Captain Mason, on being thus relieved, will report in person to the superintendent of the United States Military Academy, West Point, N. Y., for duty at that post.

Chapin, Alonzo R., Captain and Assistant Surgeon, is relieved from duty at Fort Hancock, Texas, and ordered to new Fort Bliss, Texas, for duty.

Winter, Francis A., First Lieutenant and Assistant Surgeon, is relieved from duty at new Fort Bliss, and from temporary duty at old Fort Bliss, Texas, and ordered to Fort Hancock, Texas, for duty at that post.

McCreery, George, Captain and Assistant Surgeon, will, upon the abandonment of Fort Sidney, Nebraska, report in person to the commanding officer at Fort D. A. Russell, Wyoming, for duty at that post.

CLEARY, PETER J. A., Major and Surgeon, is granted leave of absence for four months.

Spencer, William G., Captain and Assistant Surgeon, having been found incapacitated for active service by an army retiring board, will proceed to his home.

Town, Francis L. Lieutenant Colonel and Deputy Surgeon General, is relieved from temporary duty in the office of the Medical Director, Department of the Missouri, and will report in person to the commanding general, Department of Texas, for duty as Medical Director of that department.

WILSON, WILLIAM H., First Lieutenant and Assistant Surgeon, now on duty at Fort Leavenworth, Kansas, will proceed at once to Camp Merritt, Montana, and report for assignment to temporary duty at that post.

Baily, Joseph C., Colonel and Assistant Surgeon General, died on May 16, 1894, while en route from El Paso to San Antonio, Texas, in the line of duty.

## Society Meetings for the Coming Week:

Monday, June 4th: German Medical Society of the City of New York; Morrisania Medical Society (private), New York; Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Corning, N. Y., Academy of Medicine; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

Tuesday, June 5th: American Medical Association (first day—San Francisco); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Ogdensburgh, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Columbia (semi-annual—Chatham), Franklin (semi-annual), Herkimer (annual—Herkimer), Niagara (annual—Lockport), Orange (annual—Goshen), Saratoga (annual), Schoharie (annual), and Yates (annual), N. Y.; Eludson (Jersey City) and Warren (annual), N. J., County Medical Societies; Androscoggin, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

Wednesday, June 6th: State Medical Society of Wisconsin (first day—Milwaukee); American Medical Association (second day); Ontario Medical Association (first day—Toronto); Society of the Alumni of Bellevue Hospital, New York; Harlem Medical Association of the City of New York; New York Academy of Medicine (Section in Public Health); Medical Microscopical Society of Brooklyn; Medical Societies of the Counties of Cattaraugus (annual) and Richmond (Stapleton), N. Y.; Orleans, Vt., County Medical Society (annual); Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.

Thersday, June 7th: Rhode Island Medical Society (first day—Providence); Michigan State Medical Society (first day—Lansing); State Medical Society of Wisconsin (second day); American Medical Association (third day); Ontario Medical Association (second day); New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, June 8th: Rhode Island Medical Society (second day); Michigan State Medical Society (second day); State Medical Society of Wisconsin (third day); American Medical Association (fourth day); Brooklyn Dermatological and Genito-

# Tetters to the Editor.

GONORRHEA WITHOUT COITUS.

MONTREAL, May 26, 1894.

To the Editor of the New York Medical Journal:

Six: Being much interested by the letter from Dr. Foster Bush in your issue of April 7th on Chancre of the Genitals without Coitus, I thought that an account of a similar case which came under my care would be equally interesting.

A gentleman called upon me to request my attendance on his wife, who was suffering from great frequency and painfulness of micturition, together with a profuse yellow discharge from the vagina. On close questioning he admitted that he was then under the care of another physician for gonorrhea, which disease I found, on examining his wife, he had communicated to her, thick yellow pus being easily squeezed from the urethra. The more disagreeable symptoms were readily relieved under the usual treatment, and the patient was finally apparently cured. At my second visit this lady called my attention to her little daughter, about three years of age, whose genitals were bathed in pus, which was pouring from the vagina, and was excoriating the neighboring skin on the thighs. The mother had been kept in ignorance of her husband's unfaithfulness, and did not know until my first visit that her disease was a contagious one. She had in consequence used the same towel for herself and the child, thereby communicating the disease to the latter. At least I presume that it was communicated in this way, as the child occupied a separate bed. The discharge was very similar to that seen in the non-specific inflammation of the vulva of strumous and dirty children, with the exception that it seemed thicker and yellower than is found in the latter. This case was also somewhat difficult to cure, and I have no doubt that it spread up to the uterus and tubes. Gonorrhœa in little girls may also be the cause of atresia of the vagina, stricture of the urethra, and closure of the uterine or even of the fimbriated ends of the tubes, sometimes found in perfectly innocent and unmarried women. If this girl had been eighteen instead of three years old, I might have doubted her chastity, so that in this connection we should bear in mind the possibility of both gonorrhea and chancre occurring without A. LAPTHORN SMITH, M. D. coitus.

# Proceedings of Societies.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Third Triennial Meeting, held in Washington on Tuesday, Wednesday, Thursday, and Friday, May 29, 30, and 31, and June 1, 1894.

The President, Dr. Alfred L. Loomis, of New York, in the Chair.

Morphology as a Factor in the Study of Disease,—The first scientific session was in charge of the Association of American Anatomists, and this was the subject for discussion.

Dr. Harrison Allen, of Philadelphia, opened the discussion. He defined morphology as "anatomy writ large," and said that, although it was often said that anatomy was complete, and nothing was left to be studied or discovered, this was far from being the case. Unfortunately it was taught now just about the same as it had been a century ago, everything that could not be applied in surgery being carefully excluded from the lecture hall. As an example of the influence of morphology on the study of disease, the speaker referred to the fact that the general shape of the gouty tooth was distinctive, and that likewise certain appearances of the nails were indicative of the gouty diathesis. Many of the fanciful theories and "schools" of medicine, such as that of the humorists, would have been impossible had the system of medicine been founded on a broad basis of morphological data. As examples of ætiological factors in morphology might be mentioned such conditions as œsophageal pouch and heart failure. The former condition was due to an insufficient number of circular fibers in the lower pharynx, resulting in a yielding of the muscular wall. The second condition was exemplified in athletes, who, it was well known, owed their staying power to certain inherited minute anatomical peculiarities in the structure of the heart. Anatomical facts were like the letters of the alphabet, their chief use being, in combination, to express ideas.

It was difficult to say to just what extent structures which were degenerate became on that account predisposed to disease. In conclusion, the speaker called attention to the fact that the biological material coming under our observation was almost always that of a highly domesticated or over-acclimated nature-Man had undoubtedly undergone changes in his organization precisely like those which existed in a domesticated animal when his organization was compared with that of an ancestral form. The change in the shape and proportion of the red blood-corpuscles in anæmia was an instance of degeneracy mimicking the process of normal evolution. A comparative study of the teeth in animals and in the human being would show some of the important bearings of morphology. Perhaps the best single conclusion to be drawn from the study of morphology as a factor in the study of disease was to be found in its great value to humanity. The scientific study of race in connection with diseased action was an almost unbroken

Dr. Thomas Dwight, of Boston, said that he did not share the pessimistic views of Dr. Allen as to the position of the medical profession in general regarding the study of anatomy. The remedy was not to be found in extending the course of instruction in anatomy in our medical schools, but in the efforts of teachers to impress their students with the fact that morphology had many practical applications in the study of disease. By so doing the student's horizon was enlarged, and he was better prepared to see in later years the value of further studies in higher anatomy. The younger members of the profession were already evincing an increased interest in this study, and did not look upon anatomy with the same aversion shown by many of their seniors in the profession.

Dr. Allen had pleaded for a longer and broader course of anatomy, and there were certainly many reasons for wishing that a more extensive and accurate knowledge of morphology was generally possessed. The expert auscultator could recognize the sound produced by the vibration of a band found occasionally stretched across the middle of the right ventricle—the moderator band of the ruminant; yet not only should he be able to recognize this, but should know that this sound was no indication of even functional disturbance of the heart. It was important for the surgeon to know that a fibrous or muscular band might be found crossing the axillary artery; also

that the brachial artery might divide high up in the arm: that the diverging artery, whether the radial or the ulnar, almost always ran superficially; and that a third trochanter, by its apparent large size when felt through the soft parts, might be mistaken for an exostosis. If the importance of a knowledge of such anomalies was not sufficient, one need only recall the important bearing of the mechanics of the skeleton on the work of the orthopædic surgeon. Tho anatomy of childhood was but little known, as was well shown by the general ignorance of practitioners, who had in charge the feeding of infants, as to the rate of growth of the stomach of an infant.

Dr. FRANK BAKER, of Washington, said that it was impossible to study the phenomena of disease properly without due regard to the laws of morphology. Great advances had been made in our knowledge of the nervous system. It was possible that we might have to abandon in time the theory that the cell was the final unit of structure. If our observations could be sufficiently minute, we should probably find that the cells themselves, even in health, were as unstable as the drops of the ocean. Inflammation itself, that process so intimately connected with the phenomena of disease, could not be thoroughly understood without a knowledge of the structure of the tissues involved in this process. The different phenomena of inflammation seemed to be due to the cells of the vessel walls assuming their independent activity, finally proliferating and producing granulation tissue and the dense fibrous masses which ultimately formed scar tissue. The rapidly growing science of bacteriology was only a branch of morphology, for microbes were subject to the same general laws of growth as the cells of the body.

It should be remembered that in many respects the human body was not yet fully adapted to the erect posture, and that many diseased conditions could be traced to this fact. It had long been known that the valves of the veins were not well adapted to the erect posture, and even the heart itself worked to great disadvantage, having to pump the blood to a much higher level. In the nervous system it was well known that disorders of function first appeared in the higher or more recently established portions. In a word, it might be said that morphology was a growing science, and one promising much for the elucidation of the highest problems of medicine.

Dr. Burt G. Wilder, of Ithaca, N. Y., said he had understood Dr. Allen to say that structure was the record of function and pathology the record of disordered function; in other words, that there was no psychosis without a neurosis of some kind. Certainly the tendency was for psychiatrists, when they could not find anything in the brain to account for the clinical symptoms during life, to assume that they were present in the brain nevertheless. This, he would suggest, was not scientific.

The speaker then detailed the history of a suicide whose brain he had been carefully studying for the past month. The man was an educated person, and had presented many peculiarities during life. A matter of curiosity and interest connected with his death was the fact that he had shot himself through the head twice. As might be expected, the brain disclosed the most extraordinary combination of visceral lesions that the speaker had ever seen in any brain.

He believed with Dr. Baker that the human body was far from being a completed structure; more than this—he believed it to be the province of the medical man to improve the human body in the direction of the elimination of that death-trap, the appendix vermiformis. He understood that practicing surgeons were almost unanimous in the opinion that the removal of the non-gangrenous appendix was associated with no great mor-

tality. Four years ago he had suggested that we should not only have children vaccinated, but should have them "de-appendicized." The only mammals near ourselves which were cursed with an appendix were the four anthropoid, tailless apes.

To the statement made by Dr. Dwight that nothing more should be added to the curriculum of our medical schools, he would say, "amen" and "amen." Morphology should be made a subject of common-school education. He predicted that in the near future most children before leaving the ordinary university would know fully as much about anatomy, physiology, and morphology as was now known by the average medical practitioner.

Dr. Allen said he did not wish to be considered a pessimist, but in many of our smaller cities anatomy was not so extensively used in practice as it should be. He would not add a moment to the time now given to the study of anatomy in our medical schools, but would urge the study of this subject in the preparatory schools. In his judgment, the teacher of anatomy should deal more than had been customary in the past with just such subjects as had been considered in this discussion.

(To be continued,)

#### NEW YORK NEUROLOGICAL SOCIETY.

Meeting of May 1, 1894.

The President, Dr. M. Allen Starr, in the Chair.

Hysteria,-Dr. Effertz, of Vienna, presented a woman, aged thirty-five, who for the past sixteen years had had a contraction of the fingers and hand of both upper extremities and complete anæsthesia of the face and body. The patient was readily hypnotized, and while she was in the cataleptic state the contracted hands and fingers relaxed on suggestion. While under the influence of hypnotism the woman invariably presented a double convergent strabismus, which disappeared when she was roused. On suggestion, the contractures could be made to disappear temporarily. The anæsthesia was always present, but the patient never burned or injured herself. There was no ataxia. The corneal reflex was present. The patient suffered from hystero-epilepsy, and sometimes went into a condition of trance spontaneously. With the left eye she was totally blind; with the other eye the visual field was limited, and she did not see certain colors. There was loss of hearing on one side.

Dr. W. M. Leszynsky said he had examined the patient a few days before, and could corroborate Dr. Effertz's statements regarding the case. It was impossible to test the knee-jerk, as the leg immediately became rigid. She was readily hypnotized, but he had found it very difficult to awaken her.

Dr. M. Allen Starr, the retiring president, made a few remarks in which he referred to the success of the society during the past two years and its prosperous condition at the present time. Many of the papers presented had shown a high grade of excellence and had been important additions to neurology; the discussions, too, had brought out many points of great practical value. Dr. Starr then introduced the newly elected president, Dr. E. D. Fisher.

Thrombosis of the Cerebral Arteries.—Dr. Fisher, after a few preliminary remarks in which he outlined the proposed work of the society during the coming year, read a paper on this subject. He stated that the most common causes of thrombosis of the cerebral arteries were atheroma and syphilitic endarteritis. In atheroma the large vessels at the base were

especially involved, but, on close examination, the smaller vessels, if traced up beyond the Sylvian fissure, would be found to have rigid walls which had lost their elasticity and were therefore subject to temporary interference with the course of the blood through them. This was particularly seen when Bright's disease was a complication or, indeed, as in most cases, a cause of the degeneration of the arterial walls. In syphilitic endarteritis it was said that the smaller arteries or capillaries were involved to a greater degree than in atheroma. The author would confine himself more particularly to the latter condition, associated with Bright's disease, as of late much had been written on the subject of urgenic hemiplegia.

The difficulty of diagnosticating this condition lay in the attempts to explain the distinct localization on the basis of uræmia as the cause. One might expect a paraplegia from the general effect of the poison on the cerebrum, or a general compression from the œdematous condition found in these cases, but not a localized paralysis. Autopsies had been reported, and several such had come under the author's observation, in which distinct hemiplegia had been present, and yet neither hæmorrhage nor thrombosis had been found to explain it. In most of the cases of uramic hemiplegia reported disease of the vessels had also existed, although no other lesion, except in some cases serous effusion, had been found. Again, at times healthy vessels had been found, but perhaps with no greater frequency than apparently healthy vessels were found in cases of hæmorrhage or thrombosis. It was certainly not an uncommon experience, especially in syphilitic endarteritis, to see a hemiplegia entirely clear up, leaving little if any trace by secondary changes of the previous interference with the cerebral circulation. We found the same condition not infrequently in atheromatous conditions in old people. The most rational explanation seemed to be that there was a temporary occlusion or stasis, which in the diseased state of the vessel walls permitted of a localized serous exudation, so that we might feel justified in returning to the old term serous apoplexy.

The commonly accepted indication of thrombosis was a gradual onset of the paralysis, perhaps extending while the patient was still conscious and able to describe its course. The consciousness might not be affected at all, or it may be affected progressively, passing into complete coma, with stertorous respiration. This implied that a large artery had been involved. The temperature was not lowered at the onset, as a rule, as in hæmorrhage, but within twenty-four or forty-eight hours there would probably be an increase of temperature from the softening which followed. The other, later stages were not to be distinguished from those due to any other destructive lesion in the brain, except perhaps by the fact that the paralyzed parts were more frequently the seat of spasmodic movements. The loss of consciousness was explained by the anæmia of the brain and also as a result of the compression. The compression was the result of three causes: There was stasis in the vessel occluded and the veins beyond, as the latter, not receiving the vis a tergo, remained filled; there was also an exudation from the vessels which now acted as a compressive agent. The collateral circulation could hardly be considered as exerting compression on the affected part. The onset of the thrombosis was usually too gradual for us to consider the question of shock to the brain as a cause of unconsciousness. In the later stages of cerebral softening, which was now accepted as non-inflammatory and entirely dependent upon the cutting off of the blood supply, aided by compression from the exuded serum, we not infrequently found hæmorrhages in the course of thrombosis, as a result of the loss of the usual support of the healthy tissues to the already diseased vessels. This the author considered to be diagnostic of thrombosis, but which within a day or two passed into deeper coma, perhaps after the recovery of consciousness soon after the initial lesion. The autopsy revealed a hæmorrhage, probably preceded by thrombosis.

Hæmorrhagic Necrosis of the Spinal Cord.—Dr. IRA VAN Gieson stated that the subject which he wished to present for consideration was what seemed to him to be an explanation of the nature and origin of certain long, slender columns of necrosis in the spinal cord, apparently associated usually with acute myelitis. These columns of necrosis were very remarkable in that they were narrow and circumscribed, and yet they might traverse long distances of the cord, above or below a circumscribed myelitis, while the surrounding structures of the cord were normal and showed no traces of inflammation or other processes which would produce such a necrotic column. For instance, seven or eight spinal segments above or below a circumscribed focus of myelitis might be pierced by a continuous streak or narrow column of necrosis, running through either the gray or the white matter, while the segments thus traversed by the necrotic columns were quite normal, with the exception of secondary degeneration in the various fiber tracts of the white matter. In addition, these necrotic columns in the spinal cord showed a tendency to the formation of cavities in them. The tissue was liable to become so much liquefied or disintegrated by the necrotic process in places along the distribution of the column that a cavity or tiny tubular canal was produced which was sharply circumscribed and quite variable in extent.

These cases were seemingly of exceedingly rare occurrence. The author knew of but two published cases, one of which had been associated with an acute circumscribed myelitis of very sudden onset, while the second had followed a myelitis of severe traumatic origin. Both the patients lived for three or four months after the onset of the myelitis. The first case was that of Dr. C. L. Dana, published in the Alienist and Neurologist for April, 1889, under the title of Acute Transverse Myelitis with Perforating Necrosis of the Whole Dorsal Cord; Ascending and Descending Degenerations. Dr. Dana had excluded bacterial action in the formation of the perforating necrosis, and had seemed to be at a loss to determine the origin of the process. The second case was the author's, and it had been published in the Transactions of the New York Pathological Society for 1891, under the title of A Case of Traumatic Myelitis in the Lower Dorsal Region, with a Central Column of Necrosis extending above the Lesion throughout the Whole Dorsal and Cervical Regions. In this case the necrotic column and canal had had no pyogenic or other lining membrane; the case had been entirely distinct from myelosyringosis; there had been absolutely no signs of inflammation in the surrounding cord structures, and the author had been at a loss to understand the occurrence of such a long necrotic column in the midst of the normal portion of the cord.

Within the past two years he had had an opportunity of studying two cases of acute myelitis, with hæmorrhage, which afforded a very simple explanation of the lesions of perforating necrosis. In brief, this peculiar process seemed to be produced primarily by long, slender columns of spinal-cord hæmorrhage, associated occasionally with cases of acute myelitis, chiefly those of violent traumatic origin, with fracture of the spine, so that there was a more or less severe crush or bruise of the cord occurring intra vitam. Then, after a period of several weeks, these columns of hæmorrhage above or below, or extending both ways from the damaged cord segment, broke down, and perforating necrosis was the result.

a result of the loss of the usual support of the healthy tissues to
the already diseased vessels. This the author considered to be
the explanation of some cases which began with symptoms

The author then gave the histories of two cases of traumatic
spinal-cord hæmorrhage which had recently come under his observation, and showed the close relationship which they bore

to the production of these long columns of necrosis or partly necrotic canals in the spinal cord, which were thus far known as perforating necrosis. In both these cases there had been violent trauma, which fractured the spinal canal and produced a crushing bruise, with disintegration of one or more segments. Both the patients had died within forty-eight hours after the accident, thus allowing the lesions to be studied before the development of any extensive myelitis or necrosis. In the first case the lesion had consisted of a disintegration of the cord at the eighth cervical segment and hæmorrhage in the two segments above and below this, shown especially on the left side of the cord. In the second case there had been a fracture of the eighth cervical vertebra, with a crushing bruise of the first and second dorsal segments of the cord. Columnar hæmorrhages were found extending upward and downward from the crushed segments.

In the case of perforating necrosis reported by Dr. Dana there had been no history of trauma such as would give rise to these columns as the result of a crushing wound to the cord, but he had distinctly stated that the myelitis had come on so suddenly as to give rise to suspicion of hæmorrhage, and he had concluded from the clinical history that there actually had been a hæmorrhage at first.

In conclusion, Dr. Van Gieson regarded the condition of perforating necrosis as a distinct and individual lesion of the cord, due to a definite series of changes beginning with hæmorrhage. To indicate this condition and to distinguish it from other spinal lesions, he suggested the name hæmatomyeloporus.

Dr. Starr said he felt no hesitancy in accepting the explanation given regarding the origin of the condition described as perforating necrosis. There was nothing in the physics of the subject which would militate against such an explanation. The connective tissue covering the cord and holding it in had a decided thickness and consistence; it offered some opposition to the knife in the fresh state, and, no matter how extensive the crushing of the cord might be, it was rather rare at an early autopsy to find the connective tissue of the cord actually ruptured. That being the case, it was easy to understand that a hemorrhage in the cord, in taking the course described by Dr. Van Gieson, simply follows the direction of, the least resistance to pressure.

Another point of interest was that in the old cases reported by the author of the paper much of the hæmorrhage had been absorbed, leaving cavities behind. Similar cavities were met with in the brain also. This fact the speaker had seen demonstrated by Meynert. In those cases cavities existed in the lenticular nucleus; they were filled with thin serous fluid, but contained no blood. In one brain there were cavities in both lenticular nuclei. It seemed, therefore, that there might be in the brain a condition homologous to that found by Dr. Van Gieson in the cord.

Dr. G. M. Hammond said that, while in the recent cases reported by Dr. Van Gieson the evidence of hæmorrhage had been very apparent, he wished to ask whether the losions in the older cases had been hæmorrhagic, and what the pathological changes had been.

Dr. Fisher said that in traumatic cases the explanation given, that the columns of hamorrhage were due to the fact that the blood had followed the course of least resistance, would hold good; in other cases, however, in which the patient survived perhaps for several months, the perforating columns of necrosis might be due, not to an extension of the hamorrhage at the time of the injury, but to slight capillary hamorrhage leading to lack of nutrition and softening.

Dr. Van Gieson, in reply to Dr. Hammond, stated that in the older cases he had seen no traces of hemorrhage in the

cord lesions; simply a mass of necrosis. After hæmorrhage of the brain, the blood might entirely disappear within three or four months, leaving perhaps some pigmentation behind or simply a small cavity filled with serous fluid.

## PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of April 11, 1894.

Gout and the Teeth.—Henry Burghard, M. D., D. D. S., read a paper on this subject by invitation of the Board of Directors.

The paper as originally written had been entitled Diseases of the Teeth with which Medical Men should be Familiar. Since then the author had seen in the Transactions of the Pennsylvania State Dental Society an article by Dr. Brubaker which dealt at length with the question of reflex disturbances having their origin in disease of the teeth. In view of the existence of that able paper, it would be idle, he said, to attempt extensive addition.

There were two things, however, which were worthy of the respectful consideration of every physician or surgeon. By far the most common cause of trigeminal neuralgia was some disease of the teeth. This might be the exposure of supersensitive dentin, an irritation or inflammation of the tooth-pulp, any degree or type of pericementitis, and retention of fragments of the teeth after attempts at extraction. To these must be added encysted teeth or those which had such malposition that eruption was deferred or impossible.

The dentist alone was familiar with the number of cases of trifacial neuralgia, spasmodic closure of the jaws, etc., which found relief through dental ministrations.

There was too much disposition among medical men to view teeth as little more than possible signs of hereditary syphilis, and the cause of gastro-intestinal disturbance in children; beyond this the majority of physicians did not concern themselves. This did not apply to specialists in ophthalmology and rhinology; they frequently consulted with the dental practitioner for possible sources of irritation in and about the teeth.

Dr. Brubaker had quoted Galezowski to the effect "that he always examined the teeth of his patients." Certainly the most eminent men of the medical fraternity recognized what an important part the peripheral irritation arising from dental diseases played in the causation of other and more serious maladies. Every one was, of course, familiar with the work done by Dr. Miller, of Berlin, in dental bacteriology. There was another subject for consideration to which he called attention—the number and variety of pathogenic organisms which found an ideal breeding place in the human mouth. All the pyogenic cocci—those of septicæmia, of pneumonia, of actinomycosis, etc.—were among them. The longer dental disease remained uncorrected, the more flourishing the colonies of these organisms.

Another matter, simple to be sure, but one in which emiment medical men had frequently erred, was the distinction of diseases of the dental pulp and of the tooth's periosteum. The pulp of the tooth was not its tactile portion; it was rather that of special sense, the thermal; for thermal changes were about the only cause of response in the healthy pulp. The tactile function resided in the tooth's periosteum, the pericementum.

Teeth which responded to concussion or pressure had the pericementum, not the pulp. \*affected; in these cases the pericementum would be found dead, decomposing, or absent. \*Vice versa\*, those which responded to thermal change, such as a jet of cold water thrown in the cavity, had the pulp affected. In the latter case, sedatives, warm syringings, and stopping were

in order; in the former, such measures would serve to increase the difficulty through retention of irritating materials; they required antiseptic washings, such as a fifteen-volume solution of hydrogen peroxide.

After marked pericemental inflammation, abscess usually supervened. All counter-irritation in these cases should be in the mouth, localized over the gum of the affected tooth. In these cases much damage was done, even at the present day, by the use of poultices.

There was a disease of the dental periosteum which had for years attracted much attention. It was known as pyorrhœa alveolaris, or better termed phagedenic pericementitis. This disease was the cause of the loss of as many teeth as dental caries, if not more. As the name implied, it was a progressive destruction of the tooth's periosteum. Erosion of the teeth was another disorder known to dentists.

The purpose of this paper was to point out the association of these disorders with the uric-acid diathesis and their striking likeness to gouty affections.

So much confusion had arisen during the discussion of papers on this subject, all due to conflicts of definition, that two would here be premised as bases to work from. They formed the reason for such opinions as were here enunciated. Stress was laid upon this matter as it was desired to point out the probability of these dental disorders being accepted as pathognomonic of the gouty disorder. Whether gout was unquestionably present or even suspected, it was confidently believed by the writer that the dental symptoms were conclusive evidence of a condition akin to or identical with the gouty; that its three stages—tooth induration, altered secretion of the glands, and degeneration of the pericementum—were expressions which received value as diagnostic signs in the order named, representing first, the stimulative; second, the irritative; and third, the inflammatory stages of the gouty diathesis.

The uric-acid condition was one arising through faulty metabolism, causing the production and retention of an excess of uric acid in the circulating fluids, followed by the changes of tissue degeneration or those arising from the presence of a constant irritant in any member of the connective-tissue group. This left open the all-important question of the exact origin of the waste product. According to all authors, heredity played the important part as a predisposing cause. The ingestion of an undue amount of nitrogenous food or the increased consumption of malt liquors or heavy wines was the exciting cause. Prominent among the attendant disordors were fermentative dyspepsia, a complexus of symptoms known as portal engorgement, cirrhosis of the kidney, and subacute or chronic inflammation, or rather irritation, in any of the fibrous structures.

Dental erosion was a progressive loss of tooth substance through a process of decalcification, a chemical solution of the calcium salts of the teeth, evidently not associated with dental caries, which the therapeutics of caries did not check. Its action was largely confined to those portions of the teeth in contact with the labial and buccal mucous membrane.

.

Phagedenic pericementitis was a degeneration of the retentive apparatus of the teeth which arose without mechanical violence, specific virus, or the selective action of drugs, and proceeded to its termination with or without the formation of calcic deposits and true pus (although the pus and deposits were usual associates), the process terminating with the loss of the teeth. It was unusual to preface the pathology of a disease by its clinical history, but it would be clearer in this instance if he did so. The teeth attacked were dense and hard, of the variety which resisted the causes of dental caries. Men and women were allike subject to it. As a rule the disease was evident only

after the patient had attained an age of thirty or over. Although it did exist in some cases before that age, its occurrence

There were two types of this pericementitis, depending upon the portion of membrane first attacked. The commoner, and, as some erroneously suppose, the only type, began as a marginal gingivitis. The earliest symptom was a deepening of color and a softening of the gum tissue at the neck of the tooth. The inflammatory appearance was increased, and by the time the case received attention the close attachment of the gum to the tooth at this point was lost. Pockets were thus formed in which were found concretions, and pus oozed or might be pressed from the pouches. This process continued; there was degeneration of the pericementum, an inflammatory degeneration, or a molecular necrosis; increased deposits of calcium salts were found as the denudation of the tooth's root proceeded. The attachment of these teeth lessened particle by particle, thus adding another source of destructive irritation, undue mobility. One by one they lost their retentive apparatus, the pericementum, and were extruded, cast off as foreign bodies. This ended the process; there was no tendency toward extension to the maxillary periosteum. At the utmost this might be destroyed at the edges of the alveolar process and there would be a slight amount of molecular necrosis at that point in consequence. The deposits were usually hard and scaly and strongly adherent. In contradistinction to the ordinary salivary calculi, they were found beneath the gum, not on it.

The disease either persisted or recurred despite all local therapeusis. It was for this more than for any other reason that the condition had been ascribed to a constitutional cause. As for the dental erosion, there was found in teeth of good structure a loss, particle by particle, of the enamel and after this the dentin. This was tn such situations that the ordinary solvent, lactic acid, produced by the action of micro-organisms was in the least amount. This was the essential difference between erosion and caries. The process was usually seen when one of the superior anterior teeth was attacked. Commonly a groove or grooves might be seen, caused by a loss of enamel upon the labial faces of one or more of these teeth. The amount of enamel surface (that containing the greatest amount of inorganic matter) affected was greater than that of the dentin. This was the reverse of the process of dental caries. These spaces of denudation were in such situation and of such shape as to exclude any cause except that arising from altered secretion of the mucous glands about the parts. Dr. E. C. Kirk, the editor of the Dental Cosmos, who had devoted much time to investigations as to this condition, had found an almost constant association of it with gout.

In most cases there was a history of heredity and acute outbreaks. If the patient had not yet been the victim of gouty disturbance he or she did become so sooner or later. This was for disease with an incipient expression in nucous structures.

Cases were recorded of teeth in which the tissues about the necks of the teeth were intact; and yet, dissociated from any of the usual causes of pericementitis, there were seen evidences of a localized inflammation of the pericementum somewhere between the apex and the neck of the tooth. The disease area had spread until there was destruction of the entire pericementum and the tooth was lost. These cases might show no evidence of the formation of true pus until near the end, when micro-organisms gained an entrance through a loss of continuity of the tissues at the neck of the tooth.

Dr. Kirk had in his possession a tooth upon which there was a destruction of the apical half of the pericementum and much of the cementum; the remainder of the membrane was intact. In this necrotic area and near the apex had been a de-

posit—a calculus evidently formed in the pericementum, for its attachment had been so slight that it had been lost. This had prevented chemical analysis.

The deposits taken from these teeth had been analyzed. While some gave the murexide reaction, certain others, with a clear history of gout, showed not the slightest trace, being composed of phosphate of calcium.

All local causes having been found insufficient to explain the course and phenomena of this particular disease, a constitutional disorder had been deemed a necessary condition for its existence. The persistence after removal of local causes assured us in such a position. Search had been made among general diseases for one which would produce a degeneration of articulative tissue with an accompaniment of crystalline deposits. In the practice of medicine but two such diseases were known—rheumatism and gout—including here, as close associates of gout, rheumatoid arthritis and lithæmia. The pathology of rheumatism did not explain or agree with that of phagedenic pericementitis. We were thus driven by a process of exclusion to viewing gout as the predisposing cause. The question now was, Would the pathology of gout explain every stage of the dental disease?

Gout was hereditary in a large proportion of cases; not that this or any disease, except in a few rare instances, was inherited, but heredity was regarded as an expression of the transmission of a type of tissue. That women, who were not commonly the subjects of gout, were the victims of phagedenic pericementitis was not an argument against gouty origin; for rheumatoid arthritis was the form assumed by hereditary gout in women (Da Costa).

In the individual who had such a family history there was a predisposition to the formation and non-elimination of an excess of waste material of nitrogenous origin. It was rational to conceive of this process as one of gradual growth; although decided manifestations of the morbid influence of the retention of these waste products did not assert themselves before middle life, the predisposition existed, and the disease process probably extended over a period before becoming recognized, the body at large resisting the morbific influence until the power of combating it was lost at some weak point or points, and the disease asserted itself. Its effects might be so insidious that our means of discrimination were insufficient to discover any aberration from an ordinary healthy standard. Like any other general irritating substance, it might be present in any amount; all other conditions being alike, the effects were in direct proportion to the amount. Results of the action of these pathogenic materials would be most evident in peripheral parts-namely, in situations where there was a scarcity of blood-vessels surrounded by fibrous tissue, the least vascular parts being the first to suffer. According to the degree of irritation, there might be any stage of vascular perversion, from a slight increase in the flow of blood to the stasis which preceded necrosis; in the cellular elements, any stage from the stimulation which promoted constructive metamorphosis to the paralysis resulting in coagulation necrosis.

The most important of all questions relating to this matter was the exact mode of the production of these waste products. Until it was ascertained whether this was an expression of faulty food metabolism or of an incomplete retrograde tissue metamorphosis, we were in the dark. Again, what part might be performed by the excretory organs and the oxygen carriers of the blood? We might suspect the blood-corpuscles to have a close relation, as there were splenic changes present. Apropos of this, the thyreoid gland and bone marrow should also be involved, otherwise we had grounds for the formation of further hypotheses as to the physiology of the spleen.

It was by no means clear what influence the liver had in the production of gout. One would infer from reading some of Lauder Brunton's works that he had suspected that organ to be largely at fault. It was presumed that any body—any crystalline substance—resulting from causes similar to those producing uric oxide would have analogous action. It was known that xanthin, or, as it had been called, urous oxide, did form nuclei of cystic calculi.

Inflammations of fibrous structures arising from such a source were perhaps commoner than was supposed or conceded. The presence of an irritating product, such as uric acid, even in slightly increased amount, could produce widespread disorders of a not severe type, and render inexplicably obstinate many disease processes usually amenable to treatment.

For the purpose of comparison as to the active diseases, general gouty condition, and marked phagedenic pericementitis, Ebstein's theory was the best. It was a nutritive disturbance first, leading to necrosis; and urates were deposited in the necrotic area.

For the minutiæ of the dental trouble, first, the unusually hard and dense teeth were very commonly the subjects of pulp calcification. Accepting the uric-acid diathesis to be a condition long existent, there would be for some period present in the circulatory fluids an excess of the irritating waste product, uric acid. From this there would be structural alterations in peripheral parts. Stimulation of the peripheral cells of the dental pulp was followed by an increased deposit of calcic material, necessarily lessening the amount of organic matter present. The density of the dentin increased, and its vital parts decreased. This might continue until scarcely any vestige of vital matter was left within the teeth. They became of the variety which resisted dental caries. The cirrhotic process affected the parts about the teeth; the alveolar process increased in density, and the thickness and elasticity of the pericementum decreased. In this connection it would be a matter of great interest to note the structure of the teeth in young patients who had a family history of gout.

At a period during or approaching middle life, the gouty condition being present, it would manifest itself in one of two ways, the intensity of the action depending upon the amount of irritating material present and the amount of resistance offered by different tissues. Altered secretion was regarded as a milder form of disorder than tissue change. Function, in the majority of cases, was altered before structure. The presence of waste material would cause, in peripheral glands, irritation during its elimination. There were numerous mucous glands in the labial and gingival mucous membrane. These might secrete an acid capable of acting as a decalcifying agent upon the calcium salts of the teeth; this would explain the phenomena of erosion.

Function was in correspondence with structure; teeth of this type were designed for hard, vigorous use. From their structure they were exposed to two probable sources of debility: one, that they might become through their lessening vascular supply of the nature of bodies foreign to the structures which supported them; the other, it was questionable if, in civilized life, ninety per cent. of persons gave their teeth sufficient use in view of this fact, for teeth of this description doing the amount of work their structure demanded were out of the question. More than this, gouty patients were frequently gourmands, and indulged in food requiring little mastication.

Disuse and misuse were two prominent sources of debility in any part of the organism. The vital parts of such teeth would, therefore, come to a state of atony through disuse. Their resistive power to morbific agents would be weakened. Disease attacked preferably a weak part; or rather, a weak part per mitted the existence and growth of the causes of disease. According to the evolutionists' definition of life, it was questionable whether a perfectly healthy part could become the subject of disease. These organs were therefore in fit condition for the development of a disease process through their acquired debility.

The teeth and their attachments to the alveoli formed articulations, and the pericementum was the periosteum of the tooth's root and the ligament which bound it to the bony walls inclosing it—the type of tissue for which the gouty poison seemed to have selective action.

According to Ebstein, the gouty process was essentially necrotic. This was in marked gout; but there must be every stage of vascular disturbance antedating the necrosis. According to the degree of irritation would be the effects. Every medical man had seen gouty attacks, ranging from a slight metatarso-phalangeal arthritis to the variety accompanied by excruciating pain, followed by deposits in the joint. So, with the teeth, the phagedenic pericementitis might be an inflammatory degeneration or a necrosis of the fibrous-in fact, of all the articulative tissue. The waste matter was now in amount sufficient to produce structural degeneration. An early angeiomatous change would be a swelling of the intima; this, in small vessels, would markedly impede if not check the flow of blood. The tissues were starved, and to the extent of innutrition; there would be either inflammatory degeneration or molecular necrosis.

For the deposits, preceding their formation, there was an acid reaction in the necrotic area; the blood having lessened alkalinity, through the presence of an excess of uric acid, a substance insoluble in acids met the acid tissues, and uric acid or urates were deposited. As before mentioned, the tests for uric acid did not always demonstrate that substance to be present in the dental deposits. These, as analyzed by Dr. Kirk, were frequently found to be phosphate of calcium. It was probable that a small crystal of a urate had acted as an irritating point around which the calculus had formed. The deposits at the necks of teeth, just beneath the free margin of the gum, did not resemble ordinary salivary calculus or the deposits which were found near the apices of the teeth. Their probable origin had a close connection with the secretion of the mucous glands, which lay just within the border-line of the gum. As the disease progressed these encroached more and more upon the area of necrosis, or their presence formed the continued irritation which determined the persistence of the disease.

As before stated, there were cases where there were no visible signs of pus. If the disease began at the gum margin, pus was probably always formed. The analogous phenomenon of gout was the tophic abscess. Several pathogenic cocci had been isolated, but there was absolutely no evidence that the disease had such a cause.

There was a dental disease for which local explanations as to cause did not suffice. George B. Wood, Niemeyer, Garrod, Duckworth, and Bartholow, among medical men; Marshall, Peirce, Kirk, Jack, and others, among dentists, had noted the association of the disease with gout, and in very many cases a clear history of heredity and acute outbreaks. Search had not been thorough in certain instances to determine whether or not obscure gout was present. Other cases showed decided evidence of lithemia. After the removal of all visible sources of local irritation, the disease of the teeth either persisted or recurred after some lessening of the severity of the local symptoms.

Some of the cases recorded were as follows: The teeth of certain individuals, with or without a definite history of gout, had become susceptible to periosteal irritation, even an inflammation, and this in the absence of the usual local irritants.

The ingestion of an undue amount of nitrogenous food or heavy wines was followed by one of these attacks of pericementitis. Upon a withdrawal of these substances from the dietary, there was a disappearance of the local inflammation.

There was but one deduction from this: The disorder most be due to faulty metabolism. There was a local inflammation, due to the formation and retention of what should be waste product; and what more was gout? There were two elements —one, a faulty metabolism; the other, the organs of excretion did not perform their functions properly. So far as there was evidence, the latter seemed to be the element which determined an attack of gout.

Faulty metabolism might, and no doubt did cause the formation of incomplete oxidation products, and these excited disorders of a mild type in very many persons; but it was only when the organs of elimination had reached and passed the limit of their function that the weak parts gave way, and an explosive attack of gout resulted.

There was no reason why any member of the same group of substances might not play the irritant rôle; xanthin or urous oxides, uric acid or uric oxides; in excess they were both irritants. Pathological chemistry certainly gave but a meager account of the origin of both substances.

In about seventy-five per cent. of cases of true phagedenic pericementitis, dentists gave an unfavorable prognosis, and despite all local measures of therapeusis the results justified such an opinion.

This was in accordance with Ebstein's theory of gout, that the process was essentially necrotic. In any disease a prognosis was favorable to the extent to which the cause might be removed and the effects remedied. Both these objects were difficult or impossible of attainment thus far in the dental disease.

As for the question of therapeutics, there was a condition in which there were altered secretion, necrosis of certain connective tissues, with a consequent undue mobility of the teeth, the presence of necrotic material, and more or less of foreign bodies; also the continuance of the predisposing cause which acted as an excitant. The indications were, of course, the removal of all the causes; a cure could not be effected while any of them persisted. All dead and foreign materials were to be removed. All bacteria were to be destroyed, and their further action was to be made difficult or harmless. Faults of occlusion were to be remedied, and loose teeth so fixed by splints that rest of the loose organs was assured. Local vascular disturbance was to be controlled. This was as far as local measures could be carried, and the daily experience of dentists demonstrated it to be insufficient.

General treatment involved the correction of the secretion of glands of the parts about the teeth. This evidently could only be accomplished by a removal of the causes which gave rise to the formation of incomplete waste products.

The gastric and intestinal catarrh must be corrected. As the gastric disturbance was of the fermentative type, a lessening of the amount of carbohydrates in the dietary was quite as important as modifying the type of the nitrogenous ingesta.

Many of the cases gave evidence of the condition known as portal engorgement. Whether affection of the liver was the primary cause of the faulty metabolism or not was a question of the utmost importance. The changes in fibrous structures at large, such as in the tissue beneath the bronchial and pulmonary epithelium, and in the connective tissue of the kidney, etc., were not within the province of our special therapeutics. Certainly the general indication was the climination of the retained, irritating waste product. How else did colchicum act?

Many symptoms were relieved by producing an increased alkalinity of the fluids of the body. In some situations concretions were removed through the solvent action of lithium salts, but it was out of the question to hope for such a result with dental deposits. The tartrate of potassium and sodium was one of the agents used for the double purpose of producing alkalinity of the circulating fluids and acting as an eliminant through the prime vie. This fact had suggested to Dr. Kirk the advantages of replacing one of the bases of this tartrate by lithium; a lithium Rochelle salt was the result. The virtues possessed by this compound over the usual lithium salts and the officinal Rochelle salts were evident. While it performed the office of the tartrate in bringing about an increased alkalinity of the blood, there was added the uric-acid solvent, lithium. It had a mildly laxative effect. Where it had been tried there had ensued a speedy amelioration of the annoying symptoms of lithmia due to clogged excretion.

Dr. Bartholow had called attention to the value of manganese salts in the treatment of the gouty condition. They aided first in a correction of the gastric disorder, and secondly, as in the case of permanganate of potassium, increased the oxidizing function. Iron should, therefore, be doubly useful in the anæmia of the gouty diathesis. In this connection, was it not possible that certain obscure maladies relieved through the inhalation of oxygen might be cases of obscure gout, masked lithæmia?

Dr. E. C. Kirk said that as medical men and as dentists we were familiar with this question of deposits on the teeth and of the loss of teeth by such deposits, but he thought that the general public, and probably medical men, were inclined to view them all as simple tartar. Dentists recognized that there was a broad distinction to be made between the two classes of deposits—those on the crown and those on the root. or in connection with the pericemental membrane of the root. Those on the crown had, on analysis, been found to consist of calcium phosphate, with a little calcium carbonate and some organic matter. The removal of this form of deposit usually removed the irritation to the gum membrane.

On the other hand, deposits on the tooth root had been shown recently to possibly take place without any break of the attachment of the gum margin. The deposit seemed to take place in the texture of the pericementum of the root. Such deposits were, of course, irritating, and brought about an inflammatory condition running a chronic course, and ultimately, loss of the tooth took place. The association of this condition with the gouty condition, or that condition known as the uric-acid diathesis, had long been observed, but not until recently had a close connection been made out. Dr. C. M. Pierce, of this city, had some deposits from the roots of teeth carefully selected, and analyzed by Professor Congdon, of the Drexel Institute. It had been found that they contained uric acid, urates of sodium, potassium, and calcium. This discovery seemed to furnish the connecting link between this disorder and the ligamentous inflammation in other parts of the body associated with gout. On the announcement of these results, Dr. Kirk had made numerous analyses of deposits taken from the roots of teeth in gouty persons, and those in which the lithæmic condition had not been so evident. In nearly all the presence of uric acid had been demonstrated. He was not sure that it had not been present in all, for those in which he had failed to find it had been among the first cases studied, and the result might have been modified by imperfect methods of testing.

There was another point, and one which it seemed to him had not been sufficiently emphasized—viz., that where this suggestion was acted upon, and the therapeutic methods adapted to gout were instituted, marked success in the cure of this local disorder was obtained. It had long been the Gordian knot of dentistry to prevent the recurrence of this disorder, which was known as pyorrhea alveolaris. Under these circumstances he was gratified to had heard this paper. He believed that the dentist had reached a point where his partial training was insufficient to enable him to cope with this disorder. The possible relationship had been pointed out, and if it could be demonstrated that this particular form of dental disease was pathognomonic of gout, as the speaker believed it could, it formed a most important diagnostic sign of which physicians should avail themselves.

With regard to the recognition of the oral conditions in relation to the general systemic condition, he would like to call attention to a point raised by hearing the first paper of the evening. We must admit that the mouth was the port of entry for nearly all the pathogenic organisms. It seemed to him evident that the whole course of the symptoms recorded by the essayist, their order of occurrence, and the marked tendency to relapses in influenza, showed that at its inception the disease was in the mouth. The characteristic furred tongue, the aphthous ulceration of the mucous membrane, and the infection of the tonsils would all point to that, the infection of the gastrointestinal tract following as a sequel to the oral infection. It had been his habit to advise proper sterilization of the mouth with appropriate antiseptics for the purpose of preventing the recurrence of influenza. Perhaps the best antiseptic was the peroxide-of-hydrogen solution. The continued use of this agent had, he thought, prevented the recurrence of the disorder in many cases. He had reason to believe that it had done so in his own case. He had suffered through two epidemics with frequent relapses of influenza, and these had ceased after rigid care in sterilizing the mouth with hydrogen peroxide.

Dr. E. T. DARBY said that the essayist had alluded to two conditions which were present in the mouth, both of which had baffled dental practitioners for many years-namely, erosion and phagedenic pericementitis. Of the latter, Dr. Kirk had spoken at length. In regard to erosion of the teeth, we had from time immemorial been baffled in ascertaining the true cause. The essayist had pointed out some of the conditions present-namely, wasting of the enamel tissue, wasting of the dentinal tissue, and finally exposure of the pulp and loss of the tooth. We had not been satisfied with the theories which had been advanced, such as acid saliva, or the use of acids in the form of fruit and drinks, but we had looked for the cause in almost everything that we could think of, until finally we began to study the theory of gout, and the consensus of opinion of late had been that, in the majority of instances where we found erosion, we also found the gouty diathesis. As had been stated, in women it was frequently found associated with deposits in the smaller joints. In other cases gout was present in many forms, but almost invariably where there was erosion we found the gouty diathesis. Some bad gone so far as to assert that by controlling the gouty tendency they had arrested the disease. This was one of those conditions with which the dentist could not battle alone. It was one of those conditions in which the medical man could do much to modify, if not to prevent.

The speaker presumed that most medical practitioners were familiar with this condition of the teeth to a greater or lesser extent. We had doubtless noticed that wasting of the labial surface, its loss of polish, then the deep grooves that had followed upon the labial and buccal surfaces. These had been attributed to the use of the toothbrush and powder. We might have noted its progress until there were very deep grooves extending well into the body of the tooth. This was the condition which was recognized as erosion.

(To be concluded.)

Gonorrhea. Being the Translation of Blennorrhea of the Sexual Organs and its Complications. By Dr. Ernest Finger, Docent at the University of Vienna. Third Revised and Enlarged Edition. With Seven Full-page Plates in Colors and Thirty-six Wood Engravings in the Text. New York: William Wood & Company, 1894. Pp. vii-324. [Price, \$3.]

The author first reviews the history of blenorrhoea of the sexual organs, dividing it into three periods: the first, in which the disease possessed its identity until the occurrence of syphilis; the second, until 1830, when it was confounded with syphilis; and the third, since 1830, in which its identity has been recognized. The consensus of recent investigations shows that the gonococcus is found in all cases of suppuration of the mucous membranes, especially of the genitalia and conjunctiva, that are described clinically as gonorrhoeal; and it is absent in all non-gonorrhoeal processes. Further, only pus containing gonococci produces gonorrhoea, and other micro-organisms cultivated from such pus, but not identical with the gonococcus, do not produce gonorrhoea.

He indicates how the division of the urethra by the compressor muscle into an anterior and a posterior portion is of very material importance in the pathology, symptomatology, and treatment of gonorrhea in the male.

The statistics the author has collected show that in the greatest number of cases gonorrhea develops on the third day, and more than two thirds within the first week, while a period of incubation longer than fourteen days is extremely rare. He considers that the development of posterior urethritis, occurring at a time when the acuteness of the process in the anterior urethra is diminishing, favors the rapid termination of the latter.

We know of no physiological fact that justifies the author's assertion that "our social conditions make extra-marital coitus necessary for a large number of young people," or the advice regarding the prophylaxis of gonorrhea.

The author reviews the various proposed methods of treating gonorrhom. He does not consider topical interference indicated until the blenorrhagic inflammation has passed its acme, a position that we believe is desirable and tenable, though frequently violated. He advises that the intensity of topical interference should be inversely proportionate to the acuteness of the inflammation.

Chronic urethritis, the complications of gonorrhea in the male and in the female, and its complications occurring in both sexes are discussed *in extenso*.

The volume is well prepared, the translator's work is satisfactory, and the work will prove useful in contributing to a comprehensive knowledge of this important disease.

Lectures on the Surgical Disorders of the Urinary Organs. By REGINALD HARRISON, F. R. C. S. Fourth Edition, rewritten. London: J. & A. Churchill, 1893. Pp. xvi-588.

The fact that the last edition of his lectures had been out of print for some time afforded the author an opportunity to thoroughly revise them as well as to incorporate his Lettsomian Lectures of 1888 and Lectures before the Royal College of Surgeons in 1891. This has increased the size of the volume and added to the number of the illustrations.

In the lectures on urethral stricture the author countenances Hava, M.D., New Orleans. [Reexcision of the stricture in instances in which the lesion is due Medical and Surgical Journal.]

to laceration or wounds of the deep urethra. He does not consider that electrolysis is a desirable method of treatment. Gradual dilatation, he thinks, is the best treatment for the larger proportion of urethral strictures; and he is disposed to limit the performance of internal urethrotomy to cases of penile stricture and to contractions in the deep urethra in which gradual dilatation is impracticable. We note with surprise that the author finds a useful field for Holt's divulsion operation. His later experience has confirmed the favorable results he published in 1885 of combined internal urethrotomy and perineal cystotomy for recurring strictures in the penile and deep urethra, for some instances of urinary fistules, for extensive strictures, and for strictures that are complicated with toxic conditions of the urine.

The author describes in detail the methods of lithotomy and lithotrity, and, while conceding the usefulness of epicystotomy, he by no means considers it the sole operation for calculus.

These lectures afford an excellent and conservative guide to the treatment of the surgical disorders of the urinary organs. Full credit is given to those American surgeons whose names are necessarily associated with the progress that has been made in this branch of surgery, and the author finds many of our instruments of great value in operative work.

Annual Report for 1893 of the New York Ophthalmic Hospital

Report of the Rush Hospital for Consumption and Allied Diseases, from February 1, 1892, to February 1, 1894. With the second report of the Women's Board of the Rush Hospital.

The Seventeenth Annual Report of the Officers of the Retreat for the Insane, Hartford, Conn., April, 1894.

The Twenty-second Annual Report of the Board of Directors of the Zoological Society of Philadelphia.

# Miscellany.

The Leech as a Drug.—Among the papers presented at the Eleventh International Medical Congress, according to the account published in the Mercredi médical for May 9th, was one on the action of extract of leeches on the formation of thrombus, by Dr. Sahli, of Berne, who remarked that Haycraft and Dickinson had already shown that extract of leeches hindered the coagulation of the blood. The active principle of this extract, it seems, is not destroyed by heat, it is not poisonous, it is insoluble in alcohol, but soluble in water, and it is eliminated in the urine, which then possesses the property characteristic of the extract. After having anæsthetized rabbits, the author divided the jugular vein and tied its proximal ends; then with the aid of the needle of a hypodermic syringe he inserted a bristle, for the purpose of giving rise to the formation of a clot. The clot was formed at the end of twenty minutes. To hinder this coagulation, it is well to make use of the cephalic extremity of a leech; one leech's head suffices to prevent about two

ounces of rabbit's blood from coagulating. The time during which this procedure continues to be efficient is abbreviated if the kidneys are acting well. The harmlessness of intravenous injections of extract of leeches allows of therapeutical investigations in the human subject in cases of relapsing thrombosis and of infarction. As human blood coagulates a little less readily than that of the rabbit, the heads of from eighty to ninety leeches will answer for a man weighing one hundred and twenty pounds. It will be well to associate with the use of this medicament that of other agents operating upon the vascular apparatus, such as digitalis. In answer to a question, the author said that he had not yet experimented as to the action of extract of leeches on the heart or on the blood pres-

Aluminum Supports in the Treatment of Pseudarthrosis .- In the Journal des praticiens for May 12th Dr. Thiriar, of Brussels, calls attention to the use of aluminum as a medium of fixation of the fragments in cases of ununited fracture. He first relates a case of compound comminuted fracture of the middle third of the leg in which, union having failed to take place, various operative procedures were resorted to without success. Finally, after the most careful antiseptic precautions, the author cut down upon the false joint through the tissues on the inner side of the leg and detached all the soft parts, including the periosteum, from the inner surface of the tibia. Then he refreshed the ends of the fragments and united the two portions of bone by means of a sheet of aluminum about four inches long and half an inch wide, pierced with six holes, through which six broad-headed screws, half an inch long, were driven. The plate and the screws had been disinfected most minutely after having been scrubbed with soap, with ether, and with alcohol, they were heated in the flame of a spirit lamp and immediately thrown into a five-per-cent, solution of carbolic acid, The metal was well tolerated and the patient made a good recovery. Another case related is that of a woman forty-two years old, in which the fracture was just below the knee. In this case also the treatment produced a good result. The author remarks that copper was recently proposed anew by Gluck, of Berlin, for supports of this kind, but unfortunately copper is not well borne by the tissues. In 1891 Dr. Quenu resorted to aluminum, but the author is not informed as to the character of the results he obtained. Dr. Thiriar thinks that the use of aluminum will be found advantageous not only in cases of confirmed pseudarthrosis, but also in recent cases of complicated fracture where it is difficult to maintain the fragments in good coaptation.

Heat as an Adjuvant to Iodine.- In the Lancet for May 12th Dr. Dawson Turner, of Edinburgh, cites Professor Tyndall's observations as to the action of iodine in shutting off the sun's light rays, while being remarkably penetrable by the heat rays, also Major Holmes's and Captain Cunningham's reports of remarkable results obtained in the treatment of goître in India by smearing the enlarged thyreoid gland with an ointment of red iodide of mercury and then causing the patient to sit f r hours with his neck exposed to the rays of the sun or to a hot fire. On the strength of these data he suggests that when iodine is applied as a sorbefacient it is wrong to cover the part, but that on the contrary, it ought to be exposed freely to the rays of the sun or to a good fire.

Trichotillomania.-It seems that this name has been given to a morbid condition characterized by a propensity to pluck out the hairs in consequence of excessive itching. At a recent meeting of the Société de dermatologie et de syphiligraphie, a.

12th, M. Hallopeau presented a paper on this subject, giving the following conclusions: There is a morbid condition characterized by severe itching of the hairy parts of the body, with paroxysms of exacerbation. These paroxysms are accompanied by a sort of mania which leads the patient to seek relief by pulling out the hairs of the affected part. Neither the hairs nor the skin show any alteration appreciable to the naked eye; under the microscope the hairs appear normal, but some of them wander beneath the epidermis. The affection is not a variety of prurigo, for the lesions characteristic of that disease are completely wanting. The trouble is of very protracted duration and is probably incurable; the treatment that seems most soothing to the patients is that of isolating the itching parts either by means of a protective varnish or by wrapping them in India rubber.

The Pope and an Amateur Physician.—The Gazette de gynécologie for May states that a curate named Kneipp, renowned for his cures with cold water, was lately consulted by Pope Leo XIII for certain pains attributed to his advanced age. The curate advised the application of cold compresses to the knees and to the nape of the neck. This treatment produced most unfortunate results; the Pope took cold and his knees became so swollen that he was obliged to call upon his ordinary physician. Monseignor Kneipp, says our contemporary, is no longer in the odor of sanctity at the Vatican.

The American Medical Association .-- At the sessions of the Section in Surgery and Anatomy, on June 5th, 6th, 7th, and 8th, the following papers will be read: Some Surgical Sins, by Dr. John B. Roberts, of Philadelphia; The Pathology of Malignant Growths, by Dr. E. Laplace, of Philadelphia; A Critique of the Sporozoan Theory of Malignant Neoplasms from a Microtechnical Standpoint, by Dr. A. P. Ohlmacher, of Chicago; The Clinical Recognition of Malignancy in Tumors, by Dr. C. A. Wheaton, of St. Paul, and Dr. Henry W. Coe, of Portland, Oregon; The Necessity of Early Surgical Interference in Malignant Tumors, by Dr. R. A. McLean, of San Francisco; The Value of Caustics in Malignant Growths, by Dr. John Parmenter, of Buffalo, and Dr. L. Duncan Bulkley, of New York; The Radical Cure of Malignant Tumors by Operation, by Dr. J. H. Wythe, of Oakland, Cal.; The Value of Inoculations with Septic or Toxic Agents in the Treatment of Malignant Neoplasms, by Dr. John A. Wyeth, of New York; Non-malignant Stenosis of the Pylorus and Duodenum, by Dr. N. S. Scott, of Cleveland; The Early Symptoms and Diagnosis of Tubercular Joint Disease, by Dr. Emmet Rixford, of San Francisco, Dr. A. B. Judson, of New York, and Dr. A. J. Steele, of St. Louis; The Conservative Treatment of Tubercular Joints, by Dr. R. H. Sayre, of New York, Dr. Harry M. Sherman, of San Francisco, and Dr. James E. Thompson, of Galveston; The Operative Treament of Tubercular Joints, by Dr. Robert W. Lovett, of Boston; The Treatment of Tubercular Joints by Injections of Iodoform, by Dr. N. Senn, of Chicago, and Dr. Stanley Stillman, of San Francisco; The Treatment of Tubercular Joints by Injections of Corrosive Sublimate, by Dr. R. H. Plummer, of San Francisco; Common Errors in Prescribing and Applying Mechanical Apparatus, by Dr. A. E. Hoadley, of Chicago; The Causation and Prevention of Hernia, by Dr. James T. Jelks, of Hot Springs, Ark.; The Management of Reducible Hernia, by Dr. Emory Lanphear, of Kansas City, and Dr. C. M. Fenn, of San Diego, Cal.; The Treatment of Irreducible Hernia, by Dr. James B. Eagleson, of Seattle, Washington; The Treatment of Strangulated Hernia, by Dr. Joseph Ransohoff, of Cincinnati; The Radical Cure of Hernia, by Dr. W. E. B. Davis, of Birmingham, Ala., and Dr. H. O. Marcy, of report of which appears in the Journal des praticiens for May Boston; The Radical Cure of Inguinal Hernia, by Dr. A. E.

Rockey, of Portland, Oregon; Concussion of the Brain, by Dr. L. C. Lane, of San Francisco; The Treatment of Fractures of the Lower End of the Humerus, by Dr. Oscar H. Allis, of Philadelphia; The Treatment of Fractures of the Lower End of the Radius, by Dr. P. T. Connor, of Cincinnati, and Dr. C. L. Bower, of Philadelphia; The Treatment of Fractures of the Neck of the Femur, by Dr. Bedford Brown, of Alexandria, Va.; The Treatment of Fractures of the Shaft of the Femur, by Dr. Llewellyn Eliot, of Washington; The Treatment of Open or Compound Fractures, by Dr. H. H. Mudd, of St. Louis, and Dr. John B. Hamilton, of Chicago; Tendon-grafting for the Deformities following Infantile Paralysis, by Dr. S. E. Milliken, of New York; The Effects of Obstruction in Urination upon the Bladder and Kidneys, by Dr. J. William White, of Philadelphia; The Diagnosis and Treatment of Enlargement of the Prostate Gland, by Dr. Hunter McGuire, of Richmond, and Dr. William T. Belfield, of Chicago; The Symptoms and Treatment of Stone in the Bladder, by Dr. William T. Briggs, of Nashville; The Symptoms and Treatment of Tumors of the Bladder, by Dr. John B. Deaver, of Philadelphia, and Dr. C. F. Buckley, of San Francisco; The Treatment of Stricture of the Urethra, by Dr. J. Rosenstirn, of San Francisco; Carcinoma of the Urethra, with a Report of Two Cases, by Dr. H. O. Walker, of Detroit; The Pathology and Symptomatology of Hæmorrhoids, Anal Fistula, and Anal Fissure, by Dr. J. M. Mathews, of Louisville, and Dr. David Powell, of Marysville, Cal.; The Treatment of Hæmorrhoids, by Dr. Charles B. Kelsey, of New York; The Treatment of Anal Fistula, by Dr. J. McF. Gaston, of Atlanta, and Dr. G. B. Somers, of San Francisco; The Treatment of Anal Fissure, by Dr. Thomas W. Huntingdon, of Sacramento, and Dr. Lewis H. Adler, Jr., of Philadelphia; A Plea for the Early and Systematic Removal of the Inguinal Lymphatic Glands in Cases of Malignant Growths in Regions from which these Glands receive Lymphatics, by Dr. H. Reineking, of Sheboygan, Wis.; Shall it be Catgut, Silk, or Both? by Dr. A. Morgan Cartledge, of San Francisco; Electrolysis in the Treatment of Aneurysm of the Aorta, by Dr. C. M. Richter, of San Francisco; Spinal Surgery, with a Report of Two Cases of Laminectomy for Paraplegia caused by Pott's Disease, by Dr. F. C. Schaefer, of Chicago; Bloodless Vaginal Myomectomy-Partial Resection of the Bladder, including the Ureteral Opening, with Reimplantation of the Ureter, by Dr. Mayer; and The Surgical Uses of Acetanilide, by Dr. George W. Woods, of the navy.

Sugar as an Oxytocic .- In the Revue internationale de bibliographie médicale, pharmaceutique et vétérinaire for April 25th there is a summary of an article on this subject published in the Semaine médicale. On the strength of observations by Dr. Mosso and Dr. Paoletti as to the action of sugar on muscular power, Dr. Bossi conceived the idea of administering it in cases of defective uterine contraction during labor. He found that it answered the purpose well and was free from the inconveniences attending the action of ergot. In eleven cases of nterine inertia during labor an ounce of sugar dissolved in water was given, and in ten of the patients it had a most favorable effect on the pains. The ecbolic action of sugar is apparent in from twenty-five to forty-five minutes, and in many cases it is sufficiently prolonged to accomplish the expulsion of the child. In some cases it has been found necessary to give a second dose of the same amount, an hour after the first one, in order to terminate the labor. The contractions excited by sugar are always perfectly regular, and never take on a tetanic

Vaccinal Ophthalmia.—In a recent Bonn thesis Dr. Schmitz discusses this subject, founding his study upon the case

of a woman who, in consequence of carrying a vaccinated child, accidentally inoculated her eye with vaccinia. An abstract of the essay is given in the Presse médicale for May 5th. The woman was not examined until five weeks after the beginning of her trouble; she then presented ulceration of the cornea with iritis, but without special features. The author considers the lesions as of vaccinal origin, but the reporter, M. V. Morax, thinks that this is by no means demonstrated. The author has found in medical literature five cases of vaccinal keratitis and twenty-five cases of a vaccinal eruption on the evelids. When the affection develops in the eye, it generally begins by a little ulceration of the lower lid, appearing four days after the inoculation. There is edema of the eyelids, together with chemosis, which is sometimes very pronounced. The base of the ulcer is usually indurated, so as to suggest a syphilitic chancre. Then further ulcerations are developed on the margin of the lids. On watching the evolution of the ulcers, it may be noticed that they proceed from pustules which, as a rule, do not present the characteristic central depression. The patients often have certain constitutional symptoms. Then, after the lapse of from eight to ten days, recovery begins and advances very rapidly. It is uncommon to see the vaccinal eruption invade the cornea. When it does, it generally forms little ulcers bordering on the edge of the cornea. These ulcers heal without leaving scars. In five exceptional cases the lesion occupied the central portion of the cornea.

An Atypical Neurosis. - In the Centralblatt für innere Medicin for May 12th there is an abstract of an article by Dr. L. Bauer, published in the Berliner klinische Wochenschrift, giving the history of the case of a boy, thirteen years old, who had always been very irritable and for three years had been the subject of extraordinary outbursts of fury. All of a sudden he was attacked with hyperæsthesia of the right foot, which disappeared in seventeen days. Six weeks afterward the same affection seized upon the left foot, and after that there were repeated attacks affecting both feet. In two of these attacks only there was erythematous reddening of the skin of the feet. Once there was hyperæsthesia of the neck in the region of the spinal accessory nerve. Coincidently with this there arose total deafness, which lasted for thirteen months and then disappeared entirely. During the persistence of the deafness the attacks of hyperæsthesia of the feet ceased, but after its subsidence they appeared again, and at the time of the report they were accompanied by some weakness of the legs. The author is disposed to class the case as one of erythromelalgia, but the commentator, Dr. Rothmann, of Berlin, thinks it more probable that it belongs under the head of hysteria.

Gersuny's Operation for Incontinence of Urine in Women .- This operation consists in freeing the anterior portion of the mucous membrane of the urethra from the surrounding parts by an incision, twisting it more or less, and fixing it in its twisted condition by means of sutures. At a recent meeting of the K. k. Gesellschaft der Aerzte, of Vienna, a report of which appears in the Wiener klinische Wochenschrift for May 10th, Dr. Hofmokl related the case of a woman, twenty-seven years old, on whom he had performed this operation, twisting the urethra to the extent of 180°. Up to the time of the report, about a month after the operation, she had had perfect control of the urine. In the discussion Dr. von Frisch mentioned several cases in which the operation had been performed, in one of which, done by himself, the twisting had been carried to the extent of a complete turn. In this case the benefit of the operation had lasted for about six weeks. It seems from this and his further reports that the good effect of the operation is apt to be only temporary.

# Rectures and Addresses.

# THE NERVOUS SYSTEM IN DISEASE,

AND THE PRACTICE OF MEDICINE FROM A NEUROLOGICAL STANDPOINT.\*

By C. H. HUGHES, M. D.,

In this age of pre-eminent progress in every department of human research and endeavor, I congratulate you on the onward march medicine has made and is yet making toward its glorious goal-the mitigation of human misery and the mastery of disease, and especially do I congratulate you on the part American medicine has taken in the scientific triumphs of the closing century over the encompassing elements and environment adverse to man's health and strength and consequent happiness and efficiency in the affairs of life. If we look back over the passing century for only a few decades, at her contributions to the welfare of man, we find she has given more than her full quota to the common fund of human happiness. She has made physical and psychical tranquillity and power, happiness and length of days, possible to man under the strain and pressure of modern progress. She has searched out and is searching out the causes which are inimical to, or promotive of, man's strength in the battle of life. She teaches him how to evade the one and to utilize the other in power of mind and body.

As our father, Hippocrates, drove the devotees of superstition from the temple of Hygeia, and taught the people that offended gods could neither bring nor propitiated gods dispel disease, and was an example of medical hygiene in his own longevity, far beyond that of any man of his time. and as that later medical devotee of Æsculapius, and as Andreas Vesalius defied the popular prejudice and ecclesiastical power of his day at the risk of his own life, to make his first human dissection (and his unfortunate untimely death the world has never ceased to deplore), so we, his professional descendants, continue to this day breaking down and ignoring the barriers of ignorance, of prejudice, and superstition that have stood or now stand in the way of man's happiness and prosperity, unlocking the secrets of Nature's arcanum and setting the captive mind and organism free from the inthrallment of disease and the gloom of untimely death.

Substitutive inoculations, beginning with the triumph of vaccinia, for establishing tolerance and immunity from other violent diseases, are spreading the rescuing power and glory of our noble profession, and the names of Jenner and Pasteur are now immortal. And the "great white plague," consumption, with its 165,000 annual victims in this country alone, will soon be a thing of the past, through wisely applied antisepsis.

Electroscopic explorations now penetrate the dark and otherwise hidden places of the human body, making it a

\* Address in Medicine, read before the American Medical Association, at San Francisco, June 6, 1894.

glow of light to the diagnostician, while other diagnostic means—electric, physical, chemical, dynamometric, æsthesiometric, thermometric, ophthalmoscopic, larnygo-pharyngoscopic, otoscopic, microscopic, spectroscopic, oneographic, sphygmographic, auditory, percussional, and tactile diagnosis, and uranalysis—come to the aid of the modern physician in searching out disease. What would our painstaking fathers in the profession have given to have seen this day of accurate methods of determining the existence and place and boundaries and prognosis of morbid conditions? By these means, no viscus and no system of the body escapes the search-light of modern medical diagnosis.

With these aids at our command, but little, if any, of the human anatomy in health or disease is absolutely beyond the reach of our science, and scarce any part beyond some relief from the multiple resources of medical art. That noli me tangere of our ancestors, the abdominal cavity, is no longer a terra incognita to the resources of surgery, thanks to Lister, of London; McDowell, of Kentucky; Battey, of Georgia; Murphy and Senn, of Chicago; and Lane, Gross, Agnew, Frank Hamilton, and John T. Hodgen. The once-hidden recesses of the brain also are now with impunity penetrated to where our ancestors dared not go, saving lives and minds formerly doomed to destruction, thanks to Fritsch and Hitzig, of Germany; Ferrier and Horsley, of England; and Bartholow, of America, the latter having been the first physician in the world to explore and prove the truth of cerebral localization by demonstrations on the living human brain.

"The time has been that when the brains were out the man would die." But we have changed all that. With judicious neuriatic council, profound anatomical knowledge, and skillful surgery, science now penetrates to the very dwelling-place of thought and volitional motor impulses in the cerebral cortex, enabling perishing victims to be saved by the helping hand of modern neurology and cerebral surgery.

Thus does medical science move majestically onward in her benefactions, and man, her beneficiary, moves forward to his higher destiny, under her benevolent ministrations

I could not in the time allotted to this address give even an outline of general medical progress in our day, and I presume it is more appropriate and really expected that I should make an address more in the line of my special observation. Accordingly, since general practice is advanced by light from every quarter, I ask your attention to Points in the Practice of Medicine from the Standpoint of a Neurologist.

La Grippe a Toxic Neurosis.—I begin with that discomforting, distressing, disastrous, and often fatal malady, la grippe—a disease with which all of us have become painfully familiar; a malady whose insidious destructiveness has not been properly appreciated by either the public or the profession; a disease which has been laughed at and sneezed at by doctor and patient, even while death was stealthily approaching to claim the unapprehensive victim; a disease whose nervous sequences, where death

has not intercepted them, have been astonishingly various and grave. I discuss chiefly the neuropathic aspects and sequelæ of this disease. It is, in my judgment, a toxic neurosis, in its early stage a nervous fever, its later symptoms depending on the centers specially touched by its toxine.

Notwithstanding the warnings and apprehensions early aroused in the minds of a few clinicians of keen observa tion, the gravity of the grippe, especially in its toxic neuropathic sequence, is only just beginning to be generally recognized, though many months have elapsed since Julius Althaus, Symes Thompson, and W. R. Gowers, of London; Charles K. Mills, of Philadelphia; myself, and other writers first called attention, since the appearance of the late epidemics, to this now clearly demonstrable fact. long before these, in former epidemics, Theophilus Thompson (the father of Symes), and Graves, Blakiston, and Peacock had noted the prominence of the nervous symptoms, especially evidences of vagus implications. Its possible fatality in certain familiar forms is now, after a larger clinical experience, much more generally apprehended and dreaded by the profession, especially since the publication of the post-mortem findings of Kusskow, of St. Petersburg, in forty cases, and the fatal results in isolated instances reported in the journals from different sections of the country where epidemic influenza has prevailed.

Kusskow's post-mortems showed hæmorrhagic and pyæmic or septico-pyæmic results as the two forms, with purulent and gangrenous inflammation of lung tissues and frequent metastasis to other organs. Hæmorrhages and hæmatomas in the muscular tissue, parenchymatous bleedings and bleedings by diapedesis, pachymeningitis hæmorrhagica interna, in one case. In fifty per cent. of the cases, hyperæmia of the pia, also meningeal infiltration and suppurative meningitis and hæmorrhage into the lateral ventricle, and very frequently lobar pneumonia. The heart muscle was soft, friable, and anæmic.

Peritonitis was never discovered. The kidneys were found to be usually affected, the spleen contracted, the intestinal canal was unchanged. Calcification was found in the muscle cells similar to those found in typhoid lesions of the bowels, venous thrombosis more often than arterial, besides the often described pharyngo laryngeal infiltration. As the hæmorrhages were invariably unilateral, the author concludes that the lesion involves the sympathetic centers.

But these fatal endings are but little more serious than some of the results of the invasion of this disease into the region of the cerebrum, middle ear, meningeal and brain inflammation and softening, and the issue of insanity.

I have known of several cases of insanity, profound melancholia, abscess of the brain, general neuritis, facial and sciatic neuralgia and fatal paralysis (one hemiplegic), but most of the vagus in this disease and its more chronic sequelæ are largely neural. The heart failure mentioned by Wilks, and seen perhaps by most of us to end life in influenza, is also due to involvement of the vagus center in the medulla, as in so-called grippe pneumonia, which accounts for the rapid fatality of lung implication in grippe, and this heart failure also causes emboli and their consequences. The vagus center involvement accounts for "the

great and alarming prostration and cardiac weakness out of all proportion to the intensity of the fever" noted by the authorities. And those other "striking features" likewise referred to-" delirium," the great nervous manifestations, headache, pain in the back and limbs and unbearable aching and soreness like the dengue fever misery-point also to the nervous system. This, with the meningitis with which the pneumonia is associated, the neuritis and the mental disorders, disinclination to mental effort, melancholia, and insanity which follow, as well as the numerous paralyses resulting, some of which, as already noted, terminate life, point plainly to the part the nervous system plays in revealing the presence of this peculiar and rapidly traveling poison of the air, which could spread from St. Petersburg to St. Louis in the short space of a few months.\* The profound depression and the feeble intermittent pulse reveal to the neurologist the pathic power of this poison in its attack upon the vital nervous centers, and the bronchitis and the pneumonia, the swelled pharyngo-laryngeal mucous membranes, the middle ear and Eustachian catarrh, coryza, intestinal catarrh, and the nephritis, even, are no antagonizing exceptions, nor does the occasional finding of pneumococci invalidate this neuropathic view. They are seldom found in the grippe and more often elsewhere.

The grippe pneumonia, which is one of its most characteristic and fatal symptoms, is such as might come from section of the vagi, and a study of the origin and many distributions and functions of these nerves—pulmonary, cardiac, etc.—gives us lucid explanation of the phenomena of the disease not otherwise so readily understood. †

\* It is a mistake, therefore, and in the light of lately recorded experience and in that of my own limited observation, to say that "in the delicate and aged alone do we see fatal results," and it is a further mistake to attribute such results, when they do occur, "only to the intensity of the fever," as one of our most gifted and brilliant authors (Osler, Practice of Medicine, 1892) has done. His profound clinical acumen compels him, however, to add "profound depression."

† The vagus largely governs the lungs, the heart, and the circulation in this disease, and toxic irritation and depression of the medulla and pons explain most of the symptoms of la grippe. Section of both vagi above the origin of the superior laryngeal nerves is followed by loss of power in the muscles of the larynx, as well as of sensibility in the larynx, trachea, bronchi, and lungs. The reflex act of coughing is abolished, the glottis does not close, food and foreign bodies, saliva and irrespirable gases, get into the respiratory passages and cause inflammation. This was shown as far back as 1740 by Valsalva and Morgagni; also by Langallois in 1812. This has been confirmed so often since that no one now disputes it. The vessels of the lungs become surcharged with blood, owing to the labored and difficult respiration and the long distention of the lungs between inspiration and expiration, serous exudation and pulmonary cedema follow, blood exudes and pus forms in the air vesicles, and a probable paralysis of the pulmonary vasomotor nervous system takes place to add to the pulmonary engorgement through the capillary system of the lungs. The pneumonia which takes place immediately after section of the vagi was found by Michaelson, according to Landois and Sterling, to be in the lower and middle lobes; the pneumonia following section of the recurrent nerves is shown more slowly in catarrhal inflammation of the upper lobes especially. Rabbits die with symptoms of pneumonia from section of the vagus. They may live for several days, if the recurrents only are cut. Dogs live longer. If the ninth, tenth, and twelfth nerves are torn out from one side in a rabbit, death also takes place from pneumonia, according to Grünhagen.

It would be interesting, but too tedious at this time, to further follow this wandering and widely connected nerve, and note its relation and that of its near-neighbor nerves, which originate in the fourth ventricle.

All that we have thus far said has just warrant in the recorded and accepted facts of neural physiology, and the careful clinician will not fail to note their significance, and much more by study of the physiology of the other nerves whose nuclei originate in the fourth ventricle, and this nerve center when touched with its peculiar toxine in its bearing on the symptomatology of la grippe.\*

In birds the upper larynx remains closed firmly and death does not take place for eight or ten days, and then with symptoms of inanition and fatty degeneration of the heart. The heart shows cloudy swelling and waxlike degeneration. Frogs die of asphyxia under the same circumstances. Some fibers of the vagus seem to exert a trophic influence over the lungs and heart.

Unilateral section of the vagus in rabbits is followed within forty-eight hours by the appearance of yellowish-white spots in the myocardium, especially near the interventricular sæptum; on the papillary muscles and along the furrows of the coronary arteries. The muscular fibers exhibit retrogressive changes whereby their striæ disappear; they become swollen and filled with albuminous granules. After eight or ten days the interstitial tissue of these foci becomes infiltrated with small round granular cells, especially near the blood-vessels. At a later stage the interstitial connective tissue increases in amount and the musclea atrophies. No effect is produced by section of the depressor or sympathetic fibers, and Fantino thus concludes that some of the fibers of the vagus exert a trophic influence on the myocardium. The same fact is not so nearly demonstrable in regard to the lungs, but it is equally inferable.

The pulmonary branches of the vagus supply motor and sensory (cough-exciting) branches to the whole bronchial system of the lungs (the pulmonary vessels being supplied with vasomotor nerves) from the sympathetic system.

They send afferent fibers to diminish, under stimulation, the activity of vasomotor centers, and thus cause a fall of the blood pressure during forced expiration, and similar fibers to act on the inhibitory centers of the heart, and thus accelerate the heart's contractions. Simultaneous stimulation of these two sets of fibers alters the pulmonary rhythm.

The vagi also contain afferent fibers which go from the pulmonary parenchyma to the medulla, which are continually in action, stimulating the respiratory center. Consequently, section of the vagi deepens the respirations and diminishes their frequency. Stimulation of the central end of the vagus also accelerates the respirations. Labored and difficult respiration may occur either when these fibers, which excite the respiratory center reflexly, are cut off, or acting centripetally to afferent impulses proceeding upward in the vagus. Conditions determining pneumonia may therefore exist in the nervous mechanism of the lungs and in its points of origin in the cord and superimposed medulla oblongata. If the trunk of one vagus or its center is paralyzed, respirations are labored, deep, and slow, such as follow section of both. Stimulation of the cardiac branches of the vagus may cause temporary suspension of the cardiac contractions, a feeling of great depression and of impending dissolution, such as we see sometimes in grippe, and as we see in dyspeptic asthma and the abdominal frog-tapping experiment of Goltz

\* The therapeutic lesson of the neuropathic implications of influenza is rest and reconstruction (pending the search after its causative bacteria and their proper bactericide, rest and reconstruction, that phagocytosis may be promoted in the blood, chloral as the best antiseptic, hypnotic, and calmative, for even the delirious stage. In the latter, ammonii bromidum added. For the pain, the coal-tar derivative analgesics, and aweat-producing opiate combinations, the elimination of all disturbers and depressors of nerve centers entering through the blood, like the rheumatic and malarial or venereal poison.

Influenza greatly weakens the vis medicatrix of the nervous centers, permits latent tendencies and slumbering diseases to spring into active force, and leaves the patient, after the active febrile stage has passed and after what is erroneously regarded as the stage of convalescence sets in, in a state of profound neurasthenia or toxic neuratrophia, from which spring many ills. It will develop into mischievous activity a latent rheumatic gout, neuralgia, malaria, or syphilis. We may expect to combat every morbid tendency the patient is prone to before we have entirely cured him of this malady. These latent morbid aptitudes so brought into renewed activity seriously complicate la grippe and embarrass prognosis. These should be appropriately combated, to leave Nature as unembarrassed as may be possible, to contend with the devastating foe. And because of the gravity of the nerve prostration and of the nervous sequelæ, the patient should be put to bed and kept there till the fever storm is over, and in the house much longer, in order to conserve the fighting energy of the assaulted nerve centers.

This injunction should be as imperative in many cases of *grippe* as it should be in cholera, for influenza is a far graver malady in its immediate and especially remote effects on the nervous system than it at first sight appears.

Dyspepsia as a Brain Disease.—What is true of the neural relations of grippe is largely true of those of dyspepsia, a disease which, as Amariah Brigham, an American physician, was the first to show, about 1840, usually has its origin in the brain, as I have elsewhere attempted, more elaborately than I shall do at this time, to establish.

I shall only ask you here to consider it as a possible brain affection from what we know of its causes, those in whom it usually exists, and the conditions of mind, occupation, and environment of those in whom we find it most often manifest.

Dyspepsia belongs to the brain-working, brain worrying, and nerve-tone-exhausting class; to those who bother their brains and eat little or not overmuch, rather than to those who gormandize; to those who burn the midnight oil in study, do not sleep from fret and worry and from carking care, rather than to the bon-vivant high liver, and he who tarries long at the wine. It belongs to the men of affairs and women of care, to the infelicitous and the dis appointed in hope and ambition, those whose cerebro-spinal systems are inordinately strained and inadequately repaired in life's battle, so that their lower corporeal functions suffer from defective innervation of the viscera concerned in the maintenance of organic life and whose cerebro-spinal systems consequently reciprocally suffer from defective appropriating power and inadequate nutrition; but starvation alone seldom develops dyspepsia.

It is through the neural connections of the brain and stomach that the acknowledged apepsia nervosa of neurology is a clinical fact. It is thus also that the relationship of nausea to migrane as the concomitant of the latter, but so long considered the cause, is explained, and, conversely, that we understand vertigo e stomacho læso, as first described and explained by that great master in medicine, Trousseau.

The brain influences the stomach and the stomach influences the brain, but the power of the former over the latter is far greater than the latter over the former in chronic conditions.\*

To concede this influence of the nervous system over the digestive processes, we need not ignore any fact of chemico-biological research, nor shut out any of the light thrown on the subject by the distinguished American investigator, Beaumont, and those who have followed him in elucidating the functions of the stomach. On the contrary, Beaumont's investigations proved the power of the mental state over the digestive processes of Alexis St. Martin.

The liver, the kidneys, the bladder, and the bowels are similarly influenced by emotion, and the lymphatic system is likewise under nervous control, like the arterioles, by the vasomotors.

A center in the medulla also influences through the chorda tympani nerve, and probably the sympathetic, the salivary secretion. A center there also influences the action of the kidneys. The chorda tympani contains secretory and vaso-dilator fibers, the sympathetic, vaso-secretory and vaso-dilator. Salivary secretion is induced reflexly by mastication and the irritation of the presence of food in the mouth and stomach, and by the vivid remembrance of certain foods whose eating has made an agreeable impression, and by emotion.

We swallow, we digest, we sob, and vomit by means of vagus fibers, and its fibers go to the cœliac plexus, the spleen, the liver, the kidneys, and the small intestine. Œsophagismus, gastrodynia, or cardialgia, tachycardia, palpitation and angina pectoris and spleen, intestinal liver and kidneys, are influenced by this wonderful nerve, as well as asthma and exophthalmic goitre and many affections of the larynx and lower air-passages, notwithstanding the complete pathology of this wonderful nerve, and of many of the interesting diseases connected with it, may be said to be yet somewhat obscure.

The vagus and the vasomotors influence or govern circulation, respiration, and digestion.

\* Great brain and nerve strain, as in insanity, brittles the bones; grief and fright blanch the hair and face; fear paralyzes the heart, depresses temperature, causes excessive and clammy perspiration; anxiety arrests secretions and shrivels the skin; remorse wastes away the body; anger flushes the face, and so fills the brain with blood that its vessels burst and the victim falls with apoplexy; shame flushes the cheek, slows the heart and respirations; sorrow shows itself in tears; love and good fortune brighten the countenance and quicken the step and pulse, lift up the form, while adversity and remorse sadden the face, slow the pulse, bend the form, and depress the bodily movements. These things and many needless to mention show us the potency of mental influence, through its proper neural channels, on the movements of the organism. We can not deny them in regard to the stomach. On the contrary, as we see the systole of the heart arrested by emotion, so we see digestion stayed by disagreeable and depressing thought. Mental force, through psycho-neural media, pervades the body, and the stomach is not exempt from its invigorating or depressing influence over its physiological functions.

† This is just such an observation as should come more frequently from general practitioners. The vasomotor nervous system is omnipresent in its organism. It follows the vascular system to the inner
\*Med., 1893,

The dominion of the nervous system over the spleen is also evident. This fact is one of the concessions of the physiology of our day. Stimulation of the medulla leads to contraction of this organ. Not only its arteries, but the organ as a whole is maintained in a state of tonic contraction to a certain extent through the agency of the nervous system.\*

Hysteria.—No better or more familiar illustration of the possible potential relation of the nervous system to disease need be mentioned before a body of practical clinicians than that of hysteria and its neural peculiarities and associated functional disturbance of organs (that mimic of all diseases with its protean features in so many instances), its atrophies, paralyses, contractures, alternating anæsthesias, hyperæsthesias and paræsthesias, aphasias, aphonias, dysphagias, stigmata, emeses, suppressions, excesses, and perversions of excretions, nutritional, sensory, motor, psychical, visual, tactile, auditory, and emotional derangements.

Hysteria illustrates in an especially forcible manner, from the standpoint of clinical observation, how suddenly and how extensively nearly all the organs of the body may be profoundly disordered in function by morbid impression through the nervous system, and these pathological impressions, often repeated and prolonged, do sometimes develop actual and enduring organic diseases.

There is a suggestive practical lesson in this "neuromimesis" or mimic neurosis, as to the relation of the nervous system to diseases in general. As the study of this disease led Goodell to diseern and portray the nerve counterfeits of uterine disease and to say, "The crying error of the day is the mistaking of nerve disease for womb disease," so I say of disease in general, the crying error of the day is the ignoring of neuropathic implications, concomitants, and sequences of organic, visceral, and general diseases, and the mistaking of nervous for other diseases.

As any organ of the body may fail functionally and be perverted in the performance of its functions, so may we have organic derangements from frequent repetitions of functional disorder, if the trophic and vasomotor nerve centers share in the functional disturbance.

The Trophoneuroses.—Here we enter the clinical domain of the tropho and vasomotor neuroses, whose name

most recesses of the body, and the number of its morbific functional possibilities is beyond computation. Some of the vasomotor ataxias, quite familiar to practicing neurologists who have opportunity for general medical observation, have been noticed and given a clinical grouping, under the term vasomotor ataxia, by S. Solis-Cohen.—Vide American Journal of the Medical Sciences.

<sup>\*</sup>Physiologists now maintain that its metabolism is controlled directly by the nervous system, and they are far nearer than formerly to an understanding of its function, just as the same system is concerned in the bilious and glycogenic functions of the liver as we see demonstrated in the fourth ventricle puncture proof of artificial glycosuria, and exsection of the pancreas has resulted in glycosuria influencing the nervous system as profoundly as thyreoidectomy. The spleen may be diminished in size either generally by the stimulation of one of the afferent nerves, and locally by direct application of the electrodes to the surface of the organ. And Paul Gibier has produced glycosuria by psychical excitation of animals.—Vide Trans. of the N. Y. Acad. of Med., 1893.

is legion from symmetrical gangrene and local asphyxias of Raynaud's disease, to the ecchymoses, etc., pigment hypertrophies, cornifications, nævi, pigment atrophies (lepra, vitiligo, etc.), arthritic atrophies, climacteric and menstrual cutaneous swellings, etc., urticaria, angeioneurotic ædema, the night palsy of Ormerod, secretion anomalies like seborrhea, hyperidrosis, anidrosis and the occasional vasomotor disturbances of the fevers, as in typhoid, and of dropsy and anasara.\*

About all the changes which come under our eye in the skin and muscles are due to impressions made through the trophic and vasomotor nerves, influencing the circulation and growth, among which we may instance scleroderma, myxædema or cachexie pachydermique and the myopathies, pseudo hypertrophy, and progressive muscular atrophy.

Physiological Rhythm, etc.—The nervous system regulates the law of rhythm in the animal economy in both its physiological movements and pathological perversions of movement, and this fact affords us, from a neurological standpoint, important hints for the management of our patients and therapeutic suggestions, hints often overlooked in practice.

The nervous system is almost an omnipresent system of the human organism. The more we learn of it the more do we wonder at man's wondrous mechanism. The more we see of its relations to organism the more we discern of its omnipotence and of its subserviency in the workings of the human economy. It excites, it controls, it reveals, and is revealed and influenced by disease. The sensory nerve trunks and branches can be traced as clearly by neuralgia (sciatic, intercostal, trifacial, etc.), and by neuritis, as by the anatomist's scalpel; and the various paralyses reveal the channels of motor conduction and centers of origin of motor impulse, thus affording us means of diagnosis beyond the reach of our unaided vision. Thus cerebral localization has been confirmed as a fact of neurophysiology, as well as by electro-vivisection.

In the interrogation of morbid symptomatology, convulsive disturbances, tremors, subsultus, paralysis, circulatory changes, the periodicity of intermittency and remittency, temperature changes, delirium and other phenomena of the fevers, the collapse, spasm, and rice-water discharges of cholera, and even of the remote causation of cancer and of many of the dermatoses, we can not help but see how intimately associated the nervous system is with the move-

ments of the organism under the influence of disease. These phenomena may truly, in a manner, be called nervous. Certain it is that the nervous system in disease plays no insignificant part—often the most important; and to timely tranquillize and reconstruct it against the assault of the causes of disease in the organism is no small part, if not the chief part, of the physician's work, for, though the blood carry germs of deadly disease to vital nerve centers, to conserve these centers by suitable therapeutic re-enforcement against their destructive work means victory over impending dissolution.

The vis medicatrix naturæ resides in these nerve centers, and in their power to maintain, under stress of invading disease, the normal metabolism in the various organs, and as I believe, though this is not yet susceptible of scientific proof, of the furnishing and multiplying of the phagocytic hosts of conservative destruction in the healthy blood. If the blood is the life, the nervous system is likewise the life of the organism. In this dual government of the economy in health and disease, both

Are parts of one great whole, Whose life the blood is, And the nerves the soul,

if this liberty of paraphrase before employed by me may be here again permitted. If we realize this fact in our clinical conclusions and efforts at treatment, we make better practitioners at the bedside than if we seek to explain the phenomena of disease by a single factor like modern humoralism, or solidism, or visceralism, or the germ theory, absolute and unconditional. It requires something more than a morbific germ to develop disease. The other factor is an assaulted, yielding and morbidly responding organism, and back of that are the disturbed or resisting mechanisms of neural control, central or peripheral, which resist, cast out, or succumb to disease.\*

The Importance of Early recognizing Neurasthenia.—A great advance was made in clinical medicine when neurasthenia, or, as I have called it, general functional neuratrophia, was first recognized and differentiated from secondary exhaustion of the general nervous system, from the auto-toxicity of retained excretions and profound physiological brain and nerve and muscle tire. This condition, described by Van Deusen, an American physician, in 1877, followed by Beard, another American physician, in 1878, is one in which the nervous system appears to suffer

<sup>\*</sup> The term trophic disorder of muscles and organs is at present much more restricted than it manifestly will be when physiology shall have more accurately numbered and located the trophic centers, whose influence over the tone and quality of the tissues and organs is now no longer a question. Certain nerve centers and nerve fibers do undoubtedly influence the growth and repair and atrophy or decay of the tissues, and Romberg, in this discovery, has rendered medical science in its practical aspects a priceless service.

<sup>†</sup> It suggests, for instance, that we should interrogate our patients as to the normal rhythmical time for eating, defecating, and sleeping, in the administration of food, of laxatives and hypnotics, and suggest also the best part of the day for necessary disturbance of our patient with medical ministrations, ablutions, driving, exercising, etc. All habit, physiological or pathological, is bound up in the law of rhythm, and a nervous system is essential to this phenomena.

<sup>\*</sup> Certain phenomena of reflex, in clinical and surgical therapy too, are better appreciated by him who thoroughly considers the nervous system in his practice. Such an one usually recognizes two factors in the peripheral causation and the morbidly responding center, which betrays in an extraordinary manner the existence of the irritation, peripheral or central.

Benjamin Rush notes the fact that Leo X died of joy upon hearing that a great calamity had befallen the French nation, and the door-keeper of Congress died from the same cause, inducing the cerebral apoplexy upon learning of the capture of Lord Cornwallis and his army during the Revolutionary War, and the great Harvey, who discovered the circulation, died in a fit of anger. It is because impressions upon the nervous system have the power to kill that they may also engender and cure disease. This malevolent potency makes psychotherapy a benevolent possibility in practice, and no wise physician ignores it.

in its nutrition, normal stability, and power, involving the viscera and nervous system only in a functional and secondary manner.

Neurasthenia, or general functional neuratrophia, shows itself chiefly in the brain, and is psychically characterized by timidity of conduct, nervous irritability, and morbid fears, bordering on but not becoming delusions, and physically by functional atonicity of the viscera, especially of the stomach, heart, bowels, and motor and psychical areas of the brain. It is the cause and source of apepsia nervosa and of cerebro-spinal irritation, and differs from hysteria, with which it is sometimes mistakenly confounded, in being continuous and not paroxysmal and in being far more common in men than in women.

It is a conservative neurosis like migraine, saving its victims from profounder breakdown, because the individual will endure but so much and can not stand a longer strain without a period of rest and repair, whereas if he could endure more the issue would be apoplexy, paralysis, or other organic trouble. Before its recognition it was thought necessary that some organ or system (the sanguineous, hepatic, etc.) should be profoundly affected to justify a conclusion of disease, and great injustice was done its victims under designation of hypochondriasis, hysteria, simple nervousness, etc., not requiring medication. Neurasthenia is a nineteenth-century evolution in clinical medicine.\*

The Relations of Neural Overstrain to the Development of Cancer and Consumption .- The developmental relations of cancer to neural overstrain, worry, and decadence of the brain and allied nervous system have lately received renewed consideration since the writer first called attention to this singular fact in the cases of General Grant, Napoleon Bonaparte, Thomas H. Benton, and others. I believe, as I many years ago stated, that a breakdown in the central nervous system, by which its trophic and resisting powers are greatly lessened, makes possible and precedes all cases of cancer. But for this, cancer germs, if such exist, would be innocuous. The same fact is in a manner true in regard to the receptivity of phthisis and other diseases of bacillic or bacteric origin. Seeds, to germinate, must have receptive soil; and in relation to cancer, as Sims Woodhead, who believes in its parasitic causation, declares, the germs require a lowered condition of the vitality of the epithelial elements in which they make their habitat, as conditions of their growth and development. Finding a soil, they multiply, secrete their toxines, and, by their irritant action on the parts which they invade, resemble certain well-known pathogenic microbes, especially Koch's bacillus, in the degenerative processes and products which they entail.+

( To be concluded.)

#### THE

#### EXTERMINATION OF INFECTIOUS DISEASES.\*

By W. C. DEMING, M.D., WESTCHESTER, N. Y.

Many of the infectious diseases have already been exterminated or have died a natural death.

Others are only held in check, but the time of their disappearance is probably not far away. I should place among these cholera, small pox, and typhus fever.

The extermination of others has been but just begun. Typhoid fever and tuberculosis are on this list.

Still others are yet laying waste the land, and the way of their extinction has not yet been clearly shown. Scarlet fever and diphtheria are the worst of these, and it is to ask if we may not at least hope that these too will some time follow in the footsteps of the others that I have chosen to bring this subject before you in my paper.

These two diseases are now endemic over a great part of the world, and the task of getting rid of them does look mighty indeed. But that it can be done and will be done in time I have no doubt. They should at least be driven back to some isolated quarter of the globe, as we hope that cholera will be driven back upon India by the advance of sanitary civilization, there to be another penalty of sloth, ignorance, carelessness, and fanaticism.

purgo, of Turin, maintained that these parasites were encapsulated protoplasmic bodies within or without the nucleus of the cancer cell, as in the descriptions of Clarke, Sondakeritch, Walker, and others, resembling the spores of protozoa or malarial hæmatozoa, and were common to all cancers of glandular degeneration.

The peripheral neoplasms contain small parasites, the deeper, large sporocysts. Mitosis or caryocinesis is absent or scarcely perceptible where the parasites are absent or few. Dr. Shattuck (editor of the Boston Medical and Surgical Journal, the first journal to report these facts from the Eleventh International Congress), in commenting on this latter fact, says: "This shows that they (the parasites) live, but in tis sues whose vitality is low."

In this memorable discussion the following facts were opposed by Professor Cornil and others to the statements of Pio-Foa and his adherents. Cancer exists in many modified cell formations and has many nuclei resembling parasites. He asserts that Pio-Foa's parasites are metamorphosed nuclei resulting from morbid caryocinesis; that

There are found also in cancer degenerated cells whose protoplasm stains red, and which contain in place of nuclei granules, flaments or masses of nuclein, representing the different forms of indirect division, without the occurrence of achromatic filaments or of clear space around the divided nuclein. These are cell degenerations arrested in one of the phases of indirect division of the nuclei. Cornil remarked that even migrating leucocytes interposed between cancer cells had been mistaken for parasites, especially when they had retrograded and had broken up into fragments of nuclein.—Eoston Medical and Surgical Journal.

And a yet stronger criticism of the parasitic origin of cancer is the failure of inoculation experiments to generally produce cancerous reaction, as Dr. Shattuck observes.

But even successful inoculations only bring us back to that other well-attested fact—the necessity of an adaptable soil and the absence of organic resistance—which we have placed in the neural regulation and normal inhibitions of vital cerebro-spinal centers.

<sup>\*</sup> Dr. George M. Board forced the general recognition of this functional morbid state of the nervous system by the profession, though some physicians of eminence yet dispute it.

<sup>†</sup> But the question of the parasitic origin of this disease was left sub judice at the last International Congress at Rome, at the close of the most interesting and learned discussion ever held upon the subject. Pio-Foa, the referee's, advocacy of the parasiticism of cancer was ably contested by Cuzin, Duply, and Cornil. Pio-Foa, supported by Mor-

<sup>\*</sup> Read before the Hospital Graduates' Club, March 29, 1894.

June 9, 1894.]

In a general way we know how all infectious diseases might be exterminated. For example, if we could take every case of a certain one of them and keep it from every direct or indirect infectious communication with another individual susceptible to it until it became no longer infectious, and then could disinfect absolutely after it, we should then and there extinguish that disease. To do this would be easier in some of the infectious diseases than in others. In typhoid fever, cholera, and tuberculosis, for example, we have only to guard our citadel from attack at one or, at most, two gates. Thus it has been said that if every person would boil his milk and drinking water before taking it, typhoid fever would end with the cases then in existence.

The same might be said perhaps of cholera.

If also we could disinfect all tubercular sputum, how long before tuberculosis would be a curiosity?

In the case of small-pox, if everybody were vaccinated and revaccinated carefully at regular intervals, this vile dis ease, too, would soon cease to exist.

But for the unabated continuance of those other infectious diseases, scarlet fever and diphtheria, there are many reasons.

Foremost among these reasons is the probability that their infectious principles are more viable—are more resistant to unfavorable environment—than are those of many of the other infections. The germ which caused the plague, for instance, has become practically extinct, probably because it requires for its growth such excessive conditions of filth and bad hygiene and great depression of the resistant powers of the individual from famine and privation as now no longer exist.

The germ of typhus fever also undoubtedly thrives best under similar conditions. So that our improved sanitary life and our methods of isolation and disinfection are sufficient to keep it in check. But these influences have not yet become strong enough to prove too much for the viability of the poisons of diphtheria and scarlet fever.

It may not be out of place to consider here for a moment the nature of the infectious principles of these diseases. If we look first at diphtheria in the light of our latest knowledge, we find that it is caused by a specific bacillus; that this bacillus is present only in the infected mucous membrane and in the discharges from it; that actual contact of this bacillus with the unhealthy or broken mucous membrane of a susceptible individual is necessary to infection; and that if the discharges are disinfected infection of others can not occur.

In regard to the insusceptibility of healthy mucous membrane, Dr. Jacobi says that "healthy unbroken mucous membrane will resist the invasion of diphtheria"; and Dr. Thorne says, "I have a strong impression that diphtheria never attacks a healthy throat."

In regard to safety obtained by disinfection of discharges, Dr. Welch says, "there is no evidence that the breath itself is infectious"; McCullom says that "actual contact with the patient or with the discharges from the mouth and nose is necessary in order to contract diphtheria"; and Mason says that "of twenty-three doubtful cases

admitted to the diphtheria ward, although isolation was only limited, not one of the number contracted diphtheria."

Would it not be possible to question if scarlet fever also is not transmissible only in the same way, by the excretions and by the added agency of the exfoliating epidermis? Is there evidence to show that in this disease the breath, by itself, is infectious? If it is not so, then the air of a room containing a scarlet-fever patient would only be dangerous from the likelihood of its containing in its dust bacilli from material, dried and comminuted, which had been coughed up, or otherwise scattered about, or from flying epidermal scales. And if we could disinfect all these excretions and prevent the dissemination of the epidermal scales, could we not also prevent the transmission of the disease?

May I venture to suggest that the longer exposure to typhus fever, usually necessary for its transmission, may be due to the fact that in this disease there is no especial discharge from the mucous membranes and no desquamaticn of the epidermis to carry the infection? If we assume that expired air alone can not carry infection, it must probably come, in this disease, from the ordinary secretions of the mucous membranes accidentally disseminated, and perhaps from the discharges from the bowels.

In measles a contrary condition—that is, an increased secretion from the mucous membranes, freely scattered by coughing and sneezing—may account for its greater contagiousness.

A similar course of reasoning would explain the statement that whooping-cough is only contagious during a paroxysm.

My object in making these speculations is to show that, if the breath by itself alone can not carry infection, our mind makes of infection a much more material and seizable conception. It is no longer that of a deadly and noxious gas or vapor rising from the patient's breath, but that of a diffusion of small but material particles mingled with the dust, which diffusion and mingling we should be able to entirely prevent. It ought to do away with the feeling of powerlessness against an impalpable essence of infection exhaling from the infectious patient. Infection should be considered something that we can and must catch and kill.

If you have ever watched a person speaking, standing in a ray of sunlight such as shows us so plainly the particles of dust in the air of a room, you must have noticed the very fine particles of saliva that are constantly thrown out by the moving lips and tongue. You can not fail to have noticed the abundant spray from a cough or sneeze. Nothing of this occurs during breathing alone. We can readily understand, therefore, how in this way a talking, singing, coughing, or sneezing person might scatter infection, who would not do so when simply quietly breathing.

A lesson to be learned from this would be to keep an infectious patient as much as possible from talking, and to hold a cloth before the nose and mouth during coughing and sneezing.

But to resume the consideration of the reasons for the perpetuation of scarlet fever and diphtheria, let me take up the one which I consider as perhaps the most active and important of all—namely, that these are diseases of child-hood particularly, and therefore circumstances are especially favorable to their spread from mild and unrecognized cases in schools. Thus Cummings shows that in Boston, during five years, in vacation time, there was a marked decrease in the number of cases of diphtheria—a circumstance we may perhaps have usually attributed to the influence of season alone. The confined air of most schoolrooms, the use of cloth-covered books, infected clothing, unwashed drinking cups, the licking of slates, the transfer from child to child, often from mouth to mouth, of toys and other articles, and the child's natural dislike of cleanliness, all help to make schools the chief, perhaps, of the causes of infectious perpetuations.

Schoolrooms in which infectious diseases have occurred may even themselves become a continuous source of infection; as, for example, in a reported case where, in a certain schoolroom, case after case of scarlet fever arose at intervals for a long time, culminating in a severe epidemic following the opening of the room after the floor had been torn up and its infectious dust scattered about.

Dr. Thorne Thorne, in a very recent lecture before the London Sanitary Institute, shows that the mortality from diphtheria in London during the past twenty years has nearly trebled, in spite of enormous advances in sanitation. He attributes this, in part, at any rate, to compulsory education bringing children together in schools, and he cites many very interesting examples of the influence of schools on the incidence of diphtheria.

A belief in the spontaneous origin of diphtheria from bad drainage and other unsanitary conditions has probably had a deterring influence on efforts to exterminate it. This is a belief which I think we can no longer hold. Dr. William H. Welch kindly writes me in answer to my inquiry that "the evidence is altogether in favor of the view that bad hygienic conditions alone can not cause diphtheria."

Dr. Park also writes, in answer to a similar inquiry: "All the evidence that we obtain tends more and more to make us believe that every case of diphtheria has come in a direct, or perhaps very indirect, way from another case."

Dr. Thorne says that there is no direct connection between bad sewerage and diphtheria.

Dr. Thorne, however, makes the following striking statements: "That all forms of sore throat are apparently infectious, and that there is sometimes seen during prevalence of sore throats, as the disorder passes from person to person, a progressive infectiousness, finally resulting in an outbreak of diphtheria." I understand this to mean that, by successive cultivations in the human throat, an infectious principle, causing at first only clinical forms of sore throat, may end by causing clinically true diphtheria.

Such an occurrence needs bacteriological study, but is quite inexplicable, it would seem, if we suppose late accidental infection with the specific bacillus.

He also thinks that diphtheria has not yet become a stable disease, like scarlet fever and measles, and that we ought to take speedy measures to prevent its becoming so.

Lastly, it may be said that we have no proof that spe-

cific diphtheria exists in cats or other animals except as a result of inoculation. One can suppose that cats could be inoculated accidentally from a human case and carry infection in that way or by particles of expectoration or dust in their fur. But we have no evidence to show that cats or other animals need be feared as sources of infection in any other way.

The diphtheria of pigeons and fowls is not caused by the Klebs-Loeffler bacillus. Klein's assertion that the milk of cows which have been inoculated with diphtheria may contain the *Bacillus diphtheriæ* has failed to be verified by experiments which others have made.

I must here again refer to Dr. Thorne's most recent statement, which is somewhat at variance with those given above.

He traces many apparently obscure outbreaks of diphtheria to infected milk, giving as the most frequent cause of this the existence of a disease in the cow itself; which disease is characterized by a rise of temperature and by the formation of vesicles and pustules upon the udder.

He also thinks that a large number, if not indeed the great majority, of our specific diseases come to us through the lower animals, or have come from them in the past.

Want of time prevents further reference at this point to the many other causes which influence the spread of scarlet fever and diphtheria.

We come now to consider the means we must use in our fight against those infectious diseases.

Our efforts must be directed to the repression of the great causes of their continuance, and it seems to me that the first essential for the successful accomplishment of such a work is thorough organization. As a means for such organization there might be suggested the formation of a society; a society for the prevention or extermination of infectious diseases, or simply a health society, if you choose, whose chief aim should be what is expressed in the longer title.

I am of the opinion that much good could be done by such an organization.

Even if we come to have a national bureau of public health, the work of a society would still be valuable as an aid to its work, and until we do have an efficient national bureau I see no method of widely organizing sanitary work, except by the aid of a powerful society.

It is implied, if not stated, that in the carrying out of the measures presently to be mentioned the aid of such a society would be of the utmost value.

One of the first works to be undertaken and one of the great essentials in this, as in all matters in which the whole public is concerned, is the education of the public—education by the reiterated statement in every possible way of the facts that we know about the infectious diseases. I think we neglect the public too much in the matter of its medical education, and leave it to be the victim of those mercenary gentlemen whose quasi-scientific statements fill so many columns of our newspapers.

The education of the public should begin, for example, by the printing and distributing to every family in the city, in the State, in the country, of circulars telling the things that should be known about scarlet fever and diphtheria; that they are preventable diseases, because every case comes from one before it; that everybody who has to do with a case is responsible that through him no other case arise; and that, by continual watchfulness and faithfulness, every one may help to the great end of extermination; emphasizing the vast importance of schools in spreading infection, the great need for care before allowing the return to school of children who have had infectious diseases, or even sore throats, or any other illness not absolutely known to be not contagious, and the increased susceptibility of persons with disordered mouths and throats.

These circulars could be sent out yearly or oftener, repeating the same things, reporting discoveries of importance, new methods, and the work done during the year.

Lectures on these subjects could be furnished for schools and societies and other educational or popular institutions.

Such education could very properly be made part of the regular course in schools and colleges, and teachers themselves should be well instructed in these principles. Perhaps it is from the universal and systematic education of teachers, and through them of children, that we have most to hope in the future. We have something to hope, too, from the improving standard of education of medical men and sanitary officers.

Judicious publications could be systematically made in the newspapers and periodicals, and even a special popular health journal established.

The early discovery of infectious cases is of the greatest possible importance, and I know of no way of accomplishing this except by the regular visits of inspectors and the enforcement of severe penalties on persons found attempting to conceal such diseases. For example, in addition to the usual methods of reporting such cases, there should be trained inspectors, young physicians, possibly medical students, or others, who should regularly, perhaps once a week, visit every tenement and lodging house in a city and report all suspicious cases. This would also act as a check on those physicians who are not in the habit of reporting their contagious cases, and they, too, should be subject to severe penalties.

Dr. Gihon says: "The sanitary inspector is destined to become the most important agent of civic administration," referring to this officer in a general way.

I believe that immediate removal to hospital of all contagious cases is an absolute necessity to surely prevent their spread.

G. H. M. Rowe, superintendent of the Boston City Hospital, says: "Not removing a person with an infectious disease to a hospital or to some place securing absolute isolation should be held as a punishable offense against society."

Q.

We need more hospitals for scarlet fever and diphtheria, and it would be advisable to have in a town like this, for example, a number of small hospitals in different convenient parts of the city. Preferably these should be near the river or outskirts, away from habitations and where land is reasonably cheap, and they should be of severely plain hospitals should have an ambulance, and every case of scarlet fever and diphtheria should be immediately taken by them to the hospital. A possible exception might be made of cases occurring in private houses, where the inspectors were satisfied of the ability and willingness of the people to carry out proper precautions under the direction of the inspector. His power to remove should be absolute in all cases, except that dwellers in private houses should have right of appeal to a higher health officer.

It might be well also to have a special hospital for patients who could pay for their care.

Wherever the cases are treated and wherever they have been, insects of all kinds should be as far as possible excluded. The danger from insects is apparently well shown by a report by Dr. Biggs of twelve cases of cholera occurring in 1892 in the neighborhood of New York, in which seven of the cases arose in the families of butchers and, of the remaining five, all but one were in persons connected with some business of food supply.

Cats, dogs, and other animals should also be excluded, for they, too, may carry infection.

With regard to the treatment of cases, when once in a proper hospital, I have nothing to say. That may be regarded as perfected so far as the further spread of the disease is concerned.

A further necessity to prevent the dissemination of these diseases would be the removal to a place of quarantine detention of all persons known to be exposed to the affection. This would certainly be an immense undertaking at first, but it is one which would be, I think, absolutely essential to success. It would necessitate the use of an island or large grounds, where all exposed persons could be kept during the period of quarantine.

With the rapid reduction in the number of cases which, it might be reasonably hoped, would follow such radical measures, the number of persons to be quarantined would also rapidly diminish.

The next step in the management of these cases would be disinfection of the premises, the clothing, and other infected articles. The details of this work have been so nearly perfected that it is only necessary for me to refer you to such works as Nuttall's Hygienic Measures in Relation to Infectious Diseases, or Dr. Seibert's report to the Academy on Disinfection during Cholera in Berlin and Hamburg (N. Y. Med. Jour., Dec. 10, 1892), and to a paper by Dr. Biggs published in the Medical Record, July 22, 1893. Only there should be mentioned the advisability of medical inspection of the work of disinfection, as perhaps the ordinary employees of health boards are too apt to do their work perfunctorily; and also the need of plenty of disinfecting stations of the latest design and full equipment.

I might further mention the total destruction of old infectious centers and the use of a mixture of paraffin and turpentine for treating infected floors.

In country districts and small towns the execution of the above-mentioned measures would be difficult on account of the almost invariable absence of proper places to which contagious cases can be taken. Possibly, sometimes, there and simple, even temporary, construction. Each of these is a miserable pest house, but usually even that is absent.

In the past two years I have been obliged in my small town to treat two cases of small-pox in their homes.

Two other cases occurring in my practice show well the evil that may come from lack of isolating hospitals in the country. Both were cases of diphtheria. In the first case the rich lady, whose coachman was the patient, bundled him off to the city by the way of a public hack, the railroad train, and the elevated cars. The second went from her boarding house to the city on the trolley and the elevated railways.

The cost of the string of cases of diphtheria that may have started from these two can only be guessed at.

It should be part of the duty of the health society or of the national bureau to have local officers or branches in small towns for the purpose of stirring up local officials and of educating the sentiment of the people to the point of providing and maintaining isolating hospitals—for the hospital service of any town is far from complete without a department for isolating any infectious disease—or the society or the government might advance money for this purpose, as suggested by Thorne.

Once let the diminution of these diseases begin to be perceptible and it would proceed with ever-increasing rapidity under a thoroughly organized and widespread system of sanitary work and an educated popular feeling.

I wish I could refer in detail to the good work done, showing the possibility of limiting outbreaks of infectious diseases by proper measures, in Massachusetts, in Michigan, in Italy, and in some English towns, but want of time forbids. I can only refer you to the reports of the health boards of these States, to Dr. Thorne's Diphtheria; its Natural History, etc., and to a report to the Italian Government, by Dr. Panizza, in which he shows a diminution of 43·17 per cent. in infectious disease in five years as a result of the sanitary awakening in that country.

The prevention of the dangers arising in schools is a point of greatest importance, to which I wish to direct your attention for a moment.

The often-suggested plan of daily inspection of the children's throats is the first I have to mention. The usually proposed method might be modified in the following manner: It should be a part of the education required of teachers to learn how to examine throats and to know a normal throat from an abnormal one. It should then be the duty of every teacher to examine the throat of every child in her department each morning, using to depress the tongue, if necessary, a piece of thin wood, fresh for each scholar. Probably children would soon learn to show their throats without a tongue depressor, and the education of their throats thus acquired would be valuable help in allowing easy local treatment in case of contagious throat disorder at any time arising.

All cases in which the teachers should find the least suspicion of sickness should be sent to a special room to await the regular morning visit of a physician, who could determine the character of the illness and whether the child should return to school, to its home, or to the hospital. A physician could thus visit several schools in a very short time. Or, better, each school should have a different phy-

sician, living in its immediate neighborhood, whose duty it should be to visit the school at the opening hour and examine all cases sent to him by the different teachers.

Both teachers and physicians would soon become experts at this work; little time would be required for the daily examination, if each teacher had only to look at the children of her own room, and little of the physician's time would be taken up. And yet I think it would be most efficient in preventing the spread of contagion in schools. It would become a matter of pride with each teacher not to let a case of infectious disease be found undetected in her room.

It might be well also, on account of the persistence of the infectious agents of scarlet fever and diphtheria in patients and their clothes, to fix a long, arbitrary time of absence from school after recovery—as long as three months perhaps—for scarlet fever may desquamate as long as that, and tonsillar follicles and recesses of the nasal cavities may hold the Bacillus diphtheriæ probably long after bacteriological examination of the throat might fail to demonstrate them.

Dr. Thorne, whose words I have so often quoted, says that no child who is suffering from any form of sore throat should be allowed at school, nor even any one from the house in which that child resides.

The sanitary condition not only of schools but of all public assemblage rooms should be regulated more carefully by law in regard to plumbing, ventilation, light, cleanliness, and the character of the furnishings.

It is not so very absurd to suggest that all public assemblage rooms should be built, as has been suggested for schoolrooms, with as strict attention to facilities for cleaning and ventilating as are our modern operating rooms.

A similar suggestion has been made in respect to hotels, steamboats, and other places of public accommodation.

In regard to the possibilities of the distribution of infectious diseases through our public means of transportation, there is little need for argument. That the elevated and surface cars of our city are prolific spreaders of disease is, I think, undeniable. The way of remedy is plain. We should have ampler and cleaner public transportation; no crowded, steaming elevated cars, no filthy mats, but floors so built that they could be cleaned daily by flushing with water, or, if mats are an unfortunate necessity, their frequent cleaning and disinfection by steam.

We may hope to gain something in time from an improvement in our class of tenement houses, a tendency to which is becoming certainly more evident. Among other points, the advisability of making the height of tenement houses certainly not greater than the width of the street should be considered.

Many of our tenement streets are also too narrow; but this and all other causes of street unsanitariness pale in insignificance before our elaborate and costly system of how not to clean streets.

Till these are cleaned, as in the best foreign cities, by daily flushing with volumes of clean water, I do not believe we shall approach a proper sanitary condition in cities. I' see no other way to effectually and safely clean our streets

of the filthy slime, the filthy snow, the decomposing animal and vegetable refuse, the wet or dry powdered horse manure, the tuberculous sputum, and the germs of a dozen different infections that defile them, except by flushing with water.

If the millions spent every year in running dust scattering brushing machines, carts, and dumping stations were put into the building and maintaining of pumping works scattered along the water fronts of our cities, or if some other source of supply were found to furnish water to flush them, we should then have a method of street cleaning that does clean streets.

All sources of public food supply should be subject to inspection. I would like to emphasize this particularly in regard to milk, because in numerous instances epidemics of scarlet fever and diphtheria have been traced directly to this article. I think all persons who furnish milk for the public market should be required to have a license, and their farms and animals be subject to regular inspection; that retailers of milk should do so only under a license, and that they should be required to be able to tell at any time from what source any given sample of their milk was brought. If it is right and necessary to inspect any man's business for the protection of the public it is right to inspect a milk supply. We do inspect boilers and elevators, but we peacefully allow ourselves and our children to be supplied with diluted cultures of the bacilli of typhoid fever, scarlet fever, or diphtheria.

There are many other sources of contaminated food supply. For instance, I know of a cesspool containing typhoid bacilli, from which a scavenger draws tankfuls of sewage and sells it directly to a market gardener, who uses it to fertilize his lettuce, cabbage, spinach, and celery which he sends to you in the city.

I have merely touched upon this great subject, as great as any that doctors have to handle. I hope I have not been presumptuous.

As we look back over the matter, we may ask ourselves these questions:

Would it be worth while to try, at so great cost, to fight these foes to a finish?

We have but to look at our published mortality tables to see the infinitely greater cost we are bearing all the time

Is it possible for us to win the fight?

My answer is, that it is simply a question of education, of organization, and of faithfulness.

How shall the fight be fought?

1

...

The answer to this I hope can be found in the feeble words with which I have tried to express my thoughts, and in the words of the multitude of writers on this subject whose works are springing up like blades of grass in springtime.

In conclusion, I wish, in self-support, to quote the words of Dr. Fischer, who asks the question, "Can we exterminate these infectious and contagious diseases?" and answer, "I believe we can"; of Dr. Adams, who says, "Our aim should be the ultimate extinction of all germ diseases"; and the grand words of Dr. Thomas, as true as they are inspiring: "Were I offered to-day by some great

power the accomplishment of one wish, I think that I would select the destruction of the process by which alcohol is created. . . . I would select as the wish nestling closest to my heart the abolition of alcohol. If this were denied me, I would choose the power of stamping out forever those contagious diseases which fill our graves with curly heads and dimpled cheeks and our homes with sorrow that knows no comforting. I would destroy those terrors of the household-scarlatina, diphtheria, and the host of contagious maladies which go hand in hand with them. The first of these wishes is impossible of attainment. But what of the second? Gentlemen, the way to its accomplishment is open to every man with willing hand, determined mind, and intelligent brain who stands before me now. Surely it is not too sanguine a prediction that the next century may see the extinction of contagious diseases."

# STATE AND MUNICIPAL REGULATION OF PROSTITUTION.\*

By AARON M. POWELL,

EDITOR OF THE PHILANTHROPIST AND PRESIDENT OF THE NEW YORK COMMITTEE FOR THE PREVENTION OF STATE REGULATION OF VICE.

When Dr. Sanger wrote of prostitution in 1858, the number of women living as prostitutes in the city of New York, from information given by the then Chief of Police Matsell and from other sources, was estimated to be six thousand. In a paper prepared for the World's Congress on Social Purity, held in Chicago in June, 1893, the Hon. Elbridge T. Gerry states that Superintendent Byrnes, of the Police Department, and himself compared notes with exactly the same result, and, viewing the matter from two different standpoints, they were agreed that the present number of prostitutes in New York city was at least forty thousand.

But prostitution is not an affair of one sex only. The purchasing copartners of these forty thousand prostitute women are men. How numerous these male prostitutes are can be known only approximately.

Dr. Sanger, writing of the liability to infection and of the economic aspect of prostitution, says: "The supposition that a prostitute submits to but one act of prostitution every day is 'ridiculously small.' No woman could pay her board, dress, and live in the expensive manner common among the class upon the money she would receive from one visitor daily; even two visitors is a very low estimate, and four is very far from an unreasonably large one."

If, therefore, we may accept as substantially accurate the estimate of Superintendent Byrnes and Mr. Gerry that New York has at the present time forty thousand prostitute women, and also Dr. Sanger's that four would be a reasonable estimate of the average number of daily visitors to each, we have an aggregate of at least a hundred and sixty thousand prostitute or immoral men in the metropolis.

Large as these figures appear, there is no good reason

<sup>\*</sup> Read before the Section in Public Health, Legal Medicine, and Medical and Vital Statistics of the New York Academy of Medicine, March 7, 1894.

to believe that New York, in proportion to its entire population, is immoral beyond other of our larger American cities and towns. The evil is widespread in all our large centers of population. All along the pathway of human history, in the remotest periods as in modern times, prostitution has been a conspicuous social factor. It has been and continues to be destructive not only of physical health and of the finer qualities of womanhood and manhood, but is also a great economic waste.

Dr. Sanger estimated that the average weekly income of each courtesan could not be less than ten dollars. He says: "Many pay much more than that sum for their board alone, and in first class houses it is not uncommon for a prostitute to realize as much as thirty or fifty dollars or upward in a week. But if the income is taken at the lowest point, the aggregate receipts of six thousand courtesans amount to \$60,000 per week, or \$3.120,000 per year."

If, however, there are now forty thousand courtesans in this city with an average weekly income of but ten dollars each, the cost in money to their male patrons is fully \$400,000 a week, or \$20,000,000 a year. If, as is strongly probable, the present weekly average income is at least twenty dollars, the yearly expenditure of dissolute men in New York upon prostitutes would aggregate over \$40,000,000!

But Dr. Sanger notes also another large item of expenditure in connection with prostitution—viz., for wines and liquors. He estimates that the patrons of brothels generally pay at least two thirds as much for wines and liquors as to the women inmates with whom they consort; that, at the time he wrote, the weekly outlay for liquors by the patrons of the six thousand prostitute women was fully \$40,000, or \$2,080,000 a year. That the wine and liquor expenditure in connection with the brothels of New York is relatively quite as large now as in 1858 is strongly probable. We may, therefore, properly add at least \$25,000,000 for liquors to the \$40,000,000 paid to the prostitute women of the brothels of the city, or a total outlay of fully \$65,000,000 a year in connection with prostitution.

Sensual men not only pay a heavy tribute to vice, but they stimulate a cruel traffic in dependent women and girls to supply the demand of their unrestrained passions.

#### THE STATE AND PROSTITUTION.

Of an evil of such magnitude, attended with consequences so grave as affecting the health and general welfare of the individual and of the community at large, of course the State should take cognizance. The Old World method has been for many years to license or regulate it with police and medical surveillance of prostitute women.

This government plan is based upon the assumption that vice is a necessity for men, and that a certain class of women must be set apart to minister to their lust. This sentiment was voiced by Lecky, the historian of European morals, when, referring to the woman of this victim class, he said: "Herself the supreme type of vice, she is ultimately the most efficient guardian of virtue. But for her the unchallenged purity of countless homes would be polluted, and not a few who, in the pride of their untempted

chastity, think of her with an indignant shudder, would have known the agony of remorse and despair. On that one degraded and ignoble form are concentrated the passions that might have filled the world with shame. She remains, while creeds and civilizations rise and fall, the eternal priestess of humanity, blasted for the sins of the people." If men were as bad as this picture would indicate, and the prostitute woman is the heroine she is thus painted, the judgment of society concerning her should be reversed, and, instead of being ostracised as now, she should be honored and canonized. The root of the regulation system is in the dual standard of morals, one for men and another for women, of which Lecky is an exponent.

Experience has abundantly demonstrated that this onesided plan of government regulation, which licenses a few women to pursue prostitution as a trade, subjecting them to compulsory registration, with illusory periodical examinations, while allowing their miscellaneous male patrons full liberty to disseminate disease at their will, and leaving also an always large army of clandestine prostitutes without any surveillance whatever, is worse than a sanitary failure, and serves rather to stimulate than to check prostitution itself. Law is in itself an educator, and may educate downward as well as upward. When the State, by its license and official certificate, gives to the prostitute a legal status, and at night, as in some European cities, puts up its colored signal lights in front of its brothels, it in effect consigns a victim class of its women to an odious form of slavery, digs pitfalls for its young men, and perverts the true function of government, which, as defined by Gladstone, the "Grand Old Man," is "to make it easy to do right and difficult to do wrong."

#### THE ST. LOUIS EXPERIMENT.

America has had but a single noteworthy experiment of licensing prostitution, and that was in St. Louis. Though after four years of trial it was abandoned as an ignominious failure, in both a sanitary and moral point of view, leaving the condition of the city at the last worse than at the first, it is still quoted with approval, from time to time, by American advocates of regulation. It is cited by the Director of Police of Cleveland as a justifying precedent for his disgraceful compulsory registration scheme, inaugurated a few months ago and now in operation in Cleveland, and which one of the police commissioners of this city was recently quoted as saying he should approve for New York.

It was in 1870 that the license system was inaugurated in St. Louis. The authority for it was obtained by a legislative trick, the interpolation, without debate, of the two words, "or regulate," into an amendment of the city charter, intended, as was generally supposed, to suppress prostitution. The legal effect of this amendment, as was subsequently decided by the Supreme Court of the State of Missouri, was to repeal all State laws prohibiting prostitution, so far as St. Louis was concerned, and to give to it a business status as a legitimate industry. A German municipal office-holder was deputed to visit Europe, to familiarize himself with regulation laws there. An ordinance was subsequently adopted requiring the registry of prostitute

women. The city was divided into six districts, with one medical examiner to each. The salaries of the examiners were from twelve hundred to twenty-five hundred dollars per annum. Each examiner was required to visit the houses and apartments of prostitutes, to make inquiries, and, if he thought best, physical examinations. He was to give such sanitary directions as he might deem best to render prostitution safe, and to order any of the prostitutes to be removed to the hospital whose condition, in his opinion, required it. The keepers of licensed houses were required to pay a tax of ten dollars a month, and one dollar a week for each prostitute therein; each prostitute fifty cents a week. Each registered prostitute paid about twenty-six dollars a year, and each keeper of a brothel an average of about three hundred dollars a year. As compared with the French system, the St. Louis experiment differed in appointing but a single examiner to visit, unattended, prostitute women and girls in their own houses and apartments, and there to make physical examinations, or not, at his own discretion. It is not at all surprising that the experiment excited much moral indignation and disgust on the part of good citizens-men and women-and that, so far as sanitary results were concerned, it should end in a disgraceful failure. The regulationists of St. Louis, especially those connected with its board of health, attempted to show by the figures of the earlier registrations, made at intervals of a few months, a diminution in the number of prostitutes. Dr. William G. Eliot, the honored president of Washington University of St. Louis, who made a most thorough, impartial investigation of the whole matter, says of this allegation of a diminished number of prostitutes that: "In fact, they had scotched the snake, not killed it, and in all probability the number of prostitutes had not been diminished at all. . . . To scatter a nest of hornets," he says, "is a very different thing from its destruction."

The sequel during the progress of the experiment proved an increase of thirty-four per cent, in the number of brothels, and an increase in the number of registered women of more than thirty-five per cent. There was also an undoubted increase meanwhile of clandestine prostitution. Concerning the sanitary aspect, Dr. Eliot says: "What is still more startling, when the stamping out process is examined, it appears that while the number of diseased women under treatment in 1871 was eighteen out of four hundred and eighty, or three and three fourths per cent., it has risen now (1873) to an average of forty out of six hundred and fifty-three, or over six per cent; showing the remarkable fact—to which, however, we can find a parallel in Paris itself-that even among the registered and regularly inspected prostitutes the hateful disease may increase; a result which, though unexpected, ought not to surprise us so long as the male prostitutes are themselves exempt from medical inspection." How incomplete was the registration and of how little practical value, in a sanitary point of view, the system of medical inspection was, may be seen from the significant figures presented by Dr. Eliot, taken from the reports of the chief of police of St.

1871, ending March 31st, shows that out of 3,722 females arrested, 1,526 were prostitutes and 218 keepers of bawdy houses (the Board of Health report of the same date shows 480 registered prostitutes and 99 keepers), being a total of 1,744, or forty-six per cent. of all females arrested. The year 1872 shows that out of 3,187 females arrested, 2,613 were prostitutes and 71 keepers of houses, or a total of 2,684, being over sixty-four per cent. of all females arrested, and an increase of 940 prostitutes arrested, or eighteen per cent. more than the previous year."

Dr. Edmund Andrews, of Chicago, whom you will undoubtedly recognize as good medical authority, also made a very careful investigation of the St. Louis license experiment. Commenting upon its sanitary results, he says: "The authorities in St. Louis, at the time of their effort, made a show of great diminution of venereal diseases in the hospitals and charity institutions under their control, after the license law went into operation.

"Knowing that it is easy to make a delusive show by simply exerting a pressure through the head officers to keep out some cases, and to falsify the records of others by putting down complicated cases under other heads in the record, and omitting to enter the syphilitic part as well as by calling all doubtful cases by other names, I determined to inquire of an institution not under their control. I therefore got the statistics from the United States Marine Hospital there for nearly a year before and after the time when the license law went into effect. The result was that the Marine Hospital of St. Louis showed an actual increase of the percentage of venereal diseases among its patients when the license system went into operation."

I have dwelt somewhat in detail upon the St. Louis license experiment, because it is, practically, the only important American precedent of its kind, and because of an inclination shown latterly, even at this distance of time, to use it in justification of efforts for municipal regulation, as at the present time in Cleveland, and as ominously foreshadowed in the recent comment of the Police Commissioner of this city.

When it was discovered by the better class of people of St. Louis what had been accomplished by legislative legerdemain, that license for the social evil had actually been inaugurated, much indignation was aroused and a vigorous agitation for repeal begun under the influential leadership of Dr. Eliot. A petition for repeal was signed by four thousand women of St. Louis, and presented to the Missouri Legislature. The archbishop, bishop, and Cath olic clergy, nearly all the Protestant clergy, and a majority of the St. Louis bar were enlisted in the cause of repeal. A repeal petition was signed by over a hundred and fifty physicians and lawyers. The Legislature of 1873-'74, after a prolonged and embittered discussion, finally voted the repeal by a vote of three fourths of all the members of the Senate, and in the House by ninety to one. Thus ended the license experiment in St. Louis, after having been in operation about four years.

Eliot, taken from the reports of the chief of police of St.

Louis for the years 1871 and 1872. He says: "The year have been confronted with, and defeated by, an overwhelm-

ingly adverse public opinion based upon the four years of unhappy experience.

#### REGULATION ABROAD.

It was in 1864 that by act of Parliament, supplemented by additional legislation in 1866 and again in 1869, the regulation system was introduced in Great Britain, under the name of the "Contagious Diseases Acts." They were applied to sundry military districts, ostensibly to promote the health of the army, but with the purpose on the part of their projectors, later avowed, ultimately to extend them also to the civil population. When their real character and object became known, a vigorous repeal agitation was begun, under the leadership of a gifted, noble woman, Mrs. Josephine E. Butler, which was continued for twenty years. At the end of the two decades the repeal movement was triumphant, and the acts were swept from the statute books. During the prolonged contest the battle of statistics was many times fought, and with great earnestness on both sides. Figures were employed to prove both the hygienic success and failure of the acts.

Within the proper limits of this paper I can not enter largely into the details of this statistical controversy. It was quite clearly shown that at some of the military stations under the acts there was a decline in the percentage of venereal maladies after their adoption. But it was quite as clearly shown also that this decline, from other causes, had begun prior to the passage of the acts, and that it was even greater after their passage in sundry districts not under their control. Dr. John Chapman, in the Westminster Review, in an able summary of the testimony given before a royal commission on this subject, says: "The average annual ratio of admissions to hospital on account of primary venereal sores was lessening at ten out of fourteen stations under the acts before they became operative; and in the course of definite periods before they did so, equal in length to the periods which have elapsed since the acts were put in force, the average annual ratio of admissions at those ten stations lessened 2.8 more rapidly than it did during the corresponding period since the acts were applied."

In the districts under the acts it was claimed by the advocates of regulation, and figures were cited to verify the claim, that there was a generally decreasing number of registered prostitutes and of houses of prostitution.

On the other hand it was shown that while registered prostitutes decreased, clandestine prostitutes increased; that prostitutes in the districts under the operation of the acts, who refused to register, migrated in large numbers to the adjacent districts wherein the acts were not in force, and continued to ply their vocation. More absolute power was asked for over the persons of all single or suspected women, to the end that prostitution might thus be controlled.

But the acts were opposed, and their repeal was demanded by many distinguished men and women. John Stuart Mill spoke strongly against them, and the irresponsible power delegated by them, declaring: "It is wrong to give men powers liable to abuse, and then assume that they will not be abused."

Dr. Nevins, after a most careful and exhaustive examination of the whole subject, summarizes the sanitary results of the acts as follows: "After sixteen years' adoption, the rate of improvement in primary venereal sores\* in the subjected portion of the home army was reduced from 6.7 per cent. yearly for the six recorded years before the acts, to 0.65 per cent. yearly during the sixteen years of the acts. Inefficiency in the navy (twenty thousand strong) increased from one hundred and seventy two men daily to two hundred and thirty men daily. Venereal disease rose among the registered prostitutes by above thirty-nine per cent. (from 121.6 to 169.5)."

Dr. John Simon, of whom the Right Hon. James Stansfield, the parliamentary leader for repeal, says: "No man has done more—no man has done as much—for sanitary science in this country," was appealed to by regulationists to aid the movement for the extension of the acts to the civil population. He declined, saying: "I very decidedly refrain from recommending any change in that neutral position which English law has hitherto held in regard to the venereal disease of the civil population. So far as my present knowledge enables me to judge, I believe that any departure from that position could do little but embarrass and disappoint."

The acts were not only not extended to the civil population, but were unconditionally repealed April 13, 1886. In India and some of the colonies under British rule, despite the adverse action of Parliament, regulation still continues, but in an irregular way, by the connivance of delinquent officials.

In 1871 an act was passed in India for the army there, similar to, but much more severe than, the English acts; for the fortnightly periodical examination of the women in England was replaced by a weekly or even daily examination in India, with the result, says Dr. Nevins, that the venereal diseases rose steadily year by year in the British troops in India from 196.8 per 1,000 in 1871 (the year the act was passed) to 371 per 1,000 in 1888 (the latest year officially published), an increase of eighty-eight per cent. in the seventeen years of the acts there.

Following this large increase of eighty-eight per cent., a new and startling order was issued by the commander in chief in India in June, 1886, to the commanding officer in every cantonment in India. It declared "The medical officers were to see that the examinations, etc., were strictly carried out, and the commanding officer was to take care that sufficiently numerous and sufficiently attractive prostitutes were provided for every cantonment, and that the quarters in which the women were lodged were sufficiently comfortable and attractive to satisfy the demands of both the women and the men. If their quarters do not already comply with this it was to be reported, and the deficiencies supplied as quickly as possible."

Of the sanitary results, Dr. Nevins says: "The latest

<sup>\*</sup> This one form of disease is specified because it is acknowledged in the army reports that gonorrhora was not sensibly improved by the acts in the subjected as compared with the unsubjected stations, and the comparison between the two classes of stations was never made for secondary syphilis.

officially published hospital statistics for India are for the northwestern province of India and Oudh (1886), containing fourteen large cantonments. In four of these one prostitute was provided for every seventeen men; in three of them, one for every 9.9 men; in four of them, one for every 7.25 men; and in three of them one for every 3.9 men, with the following result:

Number of stations.	Number of men to one prostitute.	Cases of all forms of venereal disease to the thousand men.		
4	17	170		
3	9 - 9	263		
4	7 · 25	402		
3	3.9	546		

"As these results are not satisfactory, still more stringent regulations are talked of as necessary."

In Continental countries there is a strong and an increasing tide of opinion against the continuance of State regulation. In Paris, Berlin, and other European capitals, which have long had police and medical surveillance of prostitutes, prostitution, and the diseases incident thereto, are most prevalent. Many an American physician can testify, if he will, of cases of infection among his own patients who, going abroad, have thought they could do with impunity in Paris in the way of sensual indulgence what at home they would hesitate to assume the risk of, because of the supposed greater safety in Paris. In Paris the police des mœurs, or so-called "Bureau of Morals," so long presided over by Lecour, the "Bismarck of the Parisian regulation administration," has been supplanted by the regular police of the city, who, under the direction of the present Prefect of Police, M. Lepine, now have the power of arresting women under the regulation code. While at the head of the police des mœurs, Lecour, with all his vigilance, was forced to acknowledge the practical failure of his system. He said:

"The administration has redoubled its activity, it has multiplied its acts of repression with regard to prostitutes, and it has definitely succeeded in maintaining a satisfactory condition of the sanitary state of public registered girls, and yet sanitary statistics prove that prostitution is increasing, and that it is becoming more dangerous to the public health."

Again, "M. Lecour, the prefect of the police des mours in Paris, in the last edition of his work on Prostitution in Paris, published about 1873, says at page 47: 'Not only the police, but all the world knows the cause of the increase of prostitution—religious feeling is weakened, and tolerance of venal and scandalous intrigues has entered into our ethics'; and at page 57 he says: We may recognize amelioration as far as outward disorder is concerned, but we are none the less sensible that the ever-rising tide of debauchery is due to causes which repression—i. e., the police—can not reach."

.

1

. .

a - i -

"Dr. Jeannel, of Bordeaux, in his work on prostitution, pages 1 and 2, bitterly reproaches M. Lecour for the increase of profligacy in Paris. He says, page 182: 'The streets of Paris and all places of public resort are crowded with the abandoned.' Page 196: 'Cabs, coffee houses, public houses, railway stations, theaters, hotels, lodging

houses, and shops are used as their lair or hunting grounds.'
Page 386: 'Scandalous scenes are enacted in the streets,
and the hospitals for venereal diseases are crowded.'" And
this, be it observed, is not the picture drawn by a "fanatic"
or an ignorant opponent of the system, but by one of its
most enthusiastic advocates.

The Municipal Council of Paris, December 28, 1880, passed a repeal resolution after long controversy, and in its preamble recited that "The Municipal Council, considering that the institution of the police des mœurs is destructive of the principle of individual liberty, without succeeding in accomplishing the end it proposes to aim at, either in the diminution of veneral diseases or in the prevention of offenses against public order," etc.

In Berlin the young German Emperor recognizes, the alarming prevalence of vice and the evils which attend it, and is disposed to encourage the efforts of the Salvation Army and other methods of reformation. In France, Switzerland, Italy, Germany, Belgium, Holland, Denmark, Sweden and Norway, a vigorous agitation has been inaugurated for the abolition of State regulation, and in sundry municipalities and localities in several of these countries abolition has already been accomplished.

THE INTERNATIONAL FEDERATION FOR THE ABOLITION OF STATE REGULATION OF VICE.

The International Federation for the Abolition of State Regulation of Vice, of which Dr. J. Birkbeck Nevins, of Liverpool, is now president, organized at a great congress held in Geneva, Switzerland, in 1877, with over five hundred delegates, representing tifteen countries, and which it was my privilege to attend as an American delegate, has now adherents in nearly every country in Europe, and also includes among its members many eminent physicians, jurists, and philanthropists. The Geneva Congress was divided into five sections, one of which, the hygienic, was presided over by Dr. De la Harpe, a distinguished physician of Lausanne. After prolonged and thorough consideration of the subject by the section, which included physicians and others familiar with the practical workings of regulation in their respective countries, its members were unanimous in adopting a series of declarations or resolutions, which have since been in substance reaffirmed by several succeeding congresses, one of which says: "The Section of Hygiene condemns, in view of their complete failure, all systems of police des maurs whose object is to regulate prostitution. The section bases its condemnation on the following among other grounds-namely, that the obligatory surgical examination of women is revolting to human nature, that it can only be carried out in the case of a certain proportion of the prostitutes, that it is impossible to rely upon this examination to discover the most serious constitutional form of venereal maladies or to hinder its progress, and that consequently it gives a false guarantee of the health of the women who are subjected to it."

Among the European physicians of high standing who are adherents of the International Federation, and whose labors in connection therewith have been influential against the continuance of the regulation system, besides its venerable president, Dr. Nevins, of Liverpool, are Dr. Moeller, of Brussels, Dr. Forel, of Zurich, Dr. Giersing, of Copenhagen, and Dr. Elizabeth Blackwell, of London.

# MUNICIPAL REGULATION IN CLEVELAND AND OTHER AMERICAN CITIES.

In this country, since the repeal of the Contagious Diseases Acts by the British Parliament, efforts to secure regulation by State action have generally been abandoned. We have latterly, however, in some cities municipal regulation, and in most police toleration of vice. In Cleveland the Director of Police has inaugurated a registration system, which is now in operation. He has already enrolled the names of upward of a thousand women and girls, who, as a condition of immunity from arrest, are required to report weekly at police headquarters, and to bring with them certificates of health. They are left at liberty to choose their own doctors for the examinations. I am advised by a Cleveland correspondent that in some cases young medical students are making these examinations for the small fee of a dollar each as a means of helping themselves along in their medical education! It is not surprising to read in the Cleveland World of February 10, 1894, that "the social evil is flourishing in Cleveland under his (Director Pollner's) rule as it has never flourished before. The women think they are exempt from arrest, and consequently are very bold." The World also says, referring to the so-called health certificates: "These examinations are usually made by young physicians with little experience, or by doctors who cater to that class of practice. They are not worth the paper they are written on, and the result is that there has been a large increase of disease during the past few months. Experienced physicians state that it is impossible to ascertain disease by any such examination, and that many people who formerly were afraid of visiting houses of this kind for fear of contracting some terrible disease, now go there frequently, thinking they are safe."

Another city wherein latterly a kindred scheme of municipal regulation has been inaugurated is Davenport, Iowa. A Davenport correspondent writes me: "The present mayor of our city requires inmates of houses of prostitution to be regularly examined by physicians, and to report any change of residence. If keepers of such houses and the inmates will appear at police stations when notified (at least once a month) and pay fines and costs, there are no arrests made either of them or visitors, unless in case of disturbance of the peace. As a result, it is reliably reported that boys, who were heretofore deterred from visiting such places for fear of it becoming known, are now to be seen in and about these places in large numbers." In Omaha the municipal authorities collect a monthly "fine" of the proprietors and women inmates of houses of debauchery, with promised immunity from arrest, which "fines," aggregating about \$24,000 a year, to give a semblance of respectability to the shameful arrangement, they appropriate to the support of their public schools!

Social vice has become an important factor in the prevalent municipal misrule. Of this fact New York furnishes a striking object lesson. With a spasmodic show of law

enforcement, made from to time, but with an obvious ulterior purpose, the police, and the municipal and political magnates who direct their action, instead of aiming at repression in good faith, really tolerate and in effect protect, for a consideration, the brothel. New York has practically, without the warrant of State law, a system, if it can be called such, of police-regulated vice.

Allied with the saloon and with the gambling evil, the brothel has become a most prolific source, not alone of physical disease and moral degradation, but also of political corruption. Municipal tampering with vice, as a substitute for repression, by irresponsible police methods, as in Cleveland, Davenport, Omaha, New York, and other American cities, is a present dangerous tendency.

#### WHAT THE STATE MAY DO.

The State can not do, and ought not to be expected to do, impossible things. It can do nothing effectively, except as law is vitalized by public opinion. It ought on no account to give to prostitution a legal status, a recognized right to be. Its aim should be the utmost restraint and ultimate abolition. It ought to be fair and just alike to women and to men. It has hitherto dealt too exclusively with women. It rightfully interdicts the brothel as the gambling den. It also rightfully prescribes punishment for the keepers of houses of public debauchery, and for those who let houses or other dwellings for such purposes. It ought vigorously to punish the incitement of minors, of either sex, to debauchery, and especially procurism-the traffic in girlhood. It ought also to severely punish the kidnapping, hiring, or corruption of minors for purposes of debauchery. Its penalties should include imprisonment as well as fine. Fines alone, in most cases, are readily paid, and amount to little more than a tax upon vice, with a minimum of restraint. Especially for the capitalists of vice, the proprietors of brothels, and the owners of property rented for their use, the prison only is of value as a deterrent. With them fines are a mere incident; the prison bars they still have a wholesome dread of.

The State and municipality ought also to provide ample hospital facilities for the treatment of venereal diseases, as readily as for all other diseases.

### THE PHYSICIAN'S OPPORTUNITY AND RESPONSIBILITY.

The physician, beyond any and all others, has it in his power to so mold public opinion, especially concerning the sanitary aspects of prostitution, as to make it practicable for wholesome repressive laws, in the interest of morality and health, to be enacted and enforced. It was the irresistible force of medical testimony against the Contagious Diseases Acts, combined with the moral protest, which rendered their final repeal inevitable. It is the weighty condemnation of the regulation system in Continental Europe by eminent physicians and sanitarians, in conjunction with moral power, which already foreshadows its abolition in the near future. So the voice of the medical profession here, directed against State and municipal complicity with vice, may and should so enlighten public opinion as to reduce public prostitution to a minimum, by making possible the

enforcement of wholesome legal restraint. There is still abroad the popular heresy that for men vice is a necessity, and that young men must sow "wild oats." What is morally wrong can not be physiologically right.

May physicians everywhere be quickened to declare, with the late Sir Andrew Clark, that immorality is not a necessity, and that chastity for all is a human possibility.

#### A CASE OF MULTIPLE PREGNANCY

WITH FORTY-SIX HOURS BETWEEN THE BIRTH OF FIRST AND SECOND CHILD.

By J. LAURENCE CALLAHAN, M. D.,

Patient, Mrs. F., primipara, aged forty-six years; married ten months; born in Ireland; always enjoyed good health. During pregnancy her health has been excellent, and she has been able to attend to her household duties up to time of confinement.

She began to have pains about 7 P.M., March 1, 1894. I was called at 11 P.M. of the same day. Upon digital examination I found the bag of waters ruptured, os fully dilated, and by palpating the abdomen I diagnosticated multiple pregnancy. The pains were regular and strong and recurring every three minutes. At 1 A.M., March 2d, I delivered her of a healthy female child.

After waiting about twenty minutes I endeavored by manipulation to bring on the expulsion of the placenta, but was unsuccessful. Pains had ceased entirely. Her pulse being normal, with no danger of hemorrhage, I decided to wait, thinking that after a few hours' rest her labor would be resumed.

After she had slept four hours I endeavored to bring on pains by external manipulation, but was unsuccessful.

She continued in this condition, with the exception of now and then a slight pain, until 10 P. M., March 2d, when she had a number of severe pains about half an hour apart, la-ting until 2 A. M., when they ceased again and returned at 3 P. M. of the same day, lasting about an hour.

At this stage of her labor, however, the os had dilated to about the size of a silver dollar.

At 9.30 P.M. the os was still very rigid during the pains, and the bag of waters very tense. As the pains were recurring every three minutes I decided to rupture the bag of waters, which I did. Her pains became more intense, and at 11 P.M., March 3d, I delivered her of a healthy male child.

After the birth of the child I was unable to secure sufficient contraction of uterus to expel the placenta; the hæmorrhage was very severe, the pulse skipping every fifth or sixth beat.

I immediately introduced my hand into the uterine cavity, extracted the placenta, and found I still had another. I reintroduced my hand and found a portion of the second placenta at tached to the uterine wall. I peeled it off gently and withdrew it with the blood clots which I found within the uterus. I am aware that such cases occur but rarely, and in all cases which I have read of the placenta has been expelled immediately after the birth of the child.

STC.

Dif-

4.

n.'

...

. .

It will be observed in this case that the cord which was attached to the first child remained in the vagina forty-six hours. This was the obstacle in the case which gave me the most anxiety, as I feared sepsis. The mother gained strength rapidly without the development of fever, and when I called, on the tenth day, I found her sitting up.

THE

# NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co.

Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 9, 1894.

THE CRAZE FOR PHOTOGRAPHY IN MEDICAL ILLUSTRATION,

We agree wholly to what a correspondent who signs himself "Medicus" says in this issue of the Journal concerning the disregard of propriety, if not of ordinary decency, that is getting to be displayed too commonly in the pictorial illustrations found in medical literature. No medical man has the slightest right to take liberties with a patient, least of all without the patient's knowledge; yet this is what the photographic apparatus, reduced to the "you-press-the-button-and-we-do-therest" stage, enables an inconsiderate person-we hesitate to say a ruthless one-to do, nay, tempts him to do. We often receive photographs showing the whole or nearly the whole of the patient's figure, although they do not purport to aid in illustrating the text of the articles they accompany further than might be accomplished by a delineation of a very limited portion of the figure. In such cases, after asking the author's consent, we suppress the unnecessary parts. Not that all these pictures, or even many of them, are objectionable on the score of indecency, for that indeed they are not; but they are or appear to be of such a character as to be capable of revealing the patient's identity, which should always be avoided. We have heard of a woman who was fond of stating to chance acquaintances that she had served as the model for the leading figure in certain well-known paintings, but the judicious recognized that this propensity of hers was morbid. The normal man and the normal woman shun the notoriety that comes from public exposure of the person, and nobody has the right to thrust such notoriety upon them. The sanctity of the person should never be violated save as a matter of necessity. This is no new dictum. The medical profession has always recognized and indorsed it, but thoughtlessness now and then allows the camera to beguile an individual into its infraction.

The truth is, it seems to us, that photography is too much used in medical illustration, quite apart from considerations of decency and of the rights of the patient. It is invaluable, no doubt, within a properly restricted sphere, but most of the conditions that writers wish to show pictorially can be brought out much more tellingly in a sketch or even a diagram. The most humiliating thing of all about the rage for photographic illustrations lies in the undeniable fact that many writers resort to them mainly to support their statements, to establish their veracity. In plain words, they say to themselves that their clinical histories are likely to rouse incredulity, and that hence they must fortify them with pictures made with the machine that "can not lie." Wholly forgetting the force of qui s'excuse s'accuse, they do not recognize to what a depth they have de-

graded themselves. Let us have photographs, then, only when they answer better than other delineations, and let us give the draughtsman's art fair play.

#### THE TREATMENT OF DIPHTHERIA.

In the Journal des sciences médicales de Lille for February 10th there is an analytical review, by Dr. G. Lemière, of various recent contributions to the periodical literature of the treatment of diphtheria. The writer begins with the self-evident statement that the number of new methods which are vaunted from time to time marks a lack of any really efficacious treatment of the disease, although there are many of these methods which, if we may believe their authors, produce marvelous results. He thus proceeds to summarize the treatments relied on by various writers whose publications he takes into account. Hubner, he says, paints the affected part two or three times a day, according to the severity of the case, with tincture of chloride of iron diluted with from one to five times its bulk of water. Then he washes the throat with limewater and applies externally iced compresses together with pieces of ice. Theoretically, tincture of chloride of iron is as powerfully antiseptic as corrosive sublimate, in so far as the microorganisms of diphtheria are concerned; according to Loeffler, it kills them instantly in a solution of 1 to 125. Moreover, its use does not involve any danger of poisoning. In fifty-two cases treated in this way, only twice did death result, and in the cases of recovery the gravity of the disease was such in six of them that the author does not hesitate to conclude that death would have supervened under any other treatment. Rosenthal gives chloride of iron internally, in a two-per-cent. solution, with the addition of glycerin, from a teaspoonful to a dessertspoonful every hour, day and night. He thinks the measure unfailing in preventing the angina from extending to the larynx. The temperature falls within twenty-four hours, the pulse becomes normal, the general condition is good, the pain is diminished, and the appetite is increased. In seventy-nine cases thus treated, only seven children died. Braun also uses sesquichloride of iron, but he is of the opinion that internal treatment alone is not enough. In order to destroy the false membranes more surely and more rapidly, we should not employ a solution, but an ointment consisting of ten parts of sesquichloride of iron and twenty parts of lanolin ointment. Two applications in the course of the day often suffice, but occasionally three are necessary. Amelioration commonly shows itself within the first twenty-four hours, and at the end of three days the disease is jugulated. While with the ordinary methods of treatment he had observed forty per cent. of deaths, he witnessed only a few with this new method.

Hornig paints the throat two or three times a day with a thirty-per-cent, watery solution of pyoctanin, and then directs the patient to take a drink at once, but not to gargle. In children it is well to avoid as much as possible allowing them to expectorate after the painting, so they should be left in bed and not carried in the arms with the head low and the legs raised, the bicycle; palpitation; ædema of the lower limbs in a person

which favors the expulsion of the pyoctanin and binders its absorption. The drug acts slowly and counteracts the poison already formed in the system. When the disease invades the nasal passages, he applies cotton tampons imbued with the same solution. He reports a hundred and forty cases thus treated; a hundred and ten observed by himself terminated favorably.

Tulle touches the false membrane every three hours with cotton tampons impregnated with a 1-to-500 solution of corrosive sublimate slightly acidulated with tartaric acid. He remarks that it is useless to seek to remove the false membrane, for it becomes detached spontaneously on the third or fourth day. At the same time he administers regularly every half hour a tenth of a grain of calomel, a grain of sodium bicarbonate, and a twentieth of a grain of ipecac until an abundant action of the bowels is produced, and thereafter repeats the dose every two hours. Besides, he gives quinine sulphate, calcium chloride, calcium citrate, and iodide of iron, in varying proportions according to the patient's age. With this treatment he reports the loss of only two children out of thirtythree.

Pilière sprays the pharynx every two hours during the day, and every three hours at night, with a 1-to-500 solution of corrosive sublimate in children over two years old and with 1-to-1,000 solution in those that are younger. He has never observed any symptoms of mercurial poisoning. He raises the pharyngeal false membranes after touching them with a tampon of absorbent cotton soaked in a 1-to-30 solution of nitrate of silver. Out of ninety-eight cases, in six of which tracheotomy was required, ninety-four ended in recovery.

Wissing employs inhalations of turpentine. He causes water to be boiled day and night in the sick-room, and adds turpentine to the water, using about six ounces in the course of a day. He also makes the patient inhale the mixed vapor directly, and says that in thirty-six hours the false membrane disappears and that poisoning never occurs. Flahaut paints the false membrane every hour or two with petroleum, taking care not to use enough of the liquid for it to trickle into the larynx. Immediately after this procedure he removes the false membrane, which seems to have become detached and dissolved under the action of the petroleum. Forty cases thus treated all terminated favorably, while in the same epidemic thirty cases treated by him according to the ordinary methods resulted in twentyone recoveries and nine deaths.

### MINOR PARAGRAPHS.

#### THE EVILS OF IMMODERATE EXERCISE.

This subject was treated of at a recent meeting of the Association pour l'avancement des sciences in a paper by M. Le Gendre, who dwelt chiefly upon the injurious effects of excessive athletic sports in the young. A summary of M. Le Gendre's paper appears in the Revue mensuelle des maladies de l'enfance for May. Among the injurious effects that he had observed were typhlitis and a general tendency to kyphosis of the cervico-dorsal region of the spine, due to excessive use of who had varices; increased violence of epistaxis; melana by rupture of the intestinal capillary in a corpulent subject; a subcutaneous hæmatoma in the region of the left iliac fossa; headache, and sleeplessness.

#### ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 5, 1894:

DISEASES.	Week ending May 29.		Week ending June 5.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	5	3	3	0
Scarlet fever	136	17	95	9
Cerebro-spinal meningitis	3	1	2	3
Measles	146	8	132	7

The St. Louis College of Physicians and Surgeons.—Dr. Emory Lanphear, for many years editor of the Kansas City Medical Index, has resigned the chair of operative surgery and clinical surgery in the Kansas City Medical College to become professor, of surgery in the St. Louis College of Physicians and Surgeons.

Sir James Paget's Golden Wedding was celebrated on May 23d, and on that day the General Medical Council passed a congratulatory resolution which, as the Lancet truly says, "gave expression to a sentiment which will be universal throughout the profession in Europe and America."

The Journal's New Quarters.—On and after the 15th instthe office of this journal will be in the publishers' new quarters, No. 72 Fifth Avenue, on the northwest corner of Thirteenth Street.

Papaw Juice (the milky juice of the Carica papaya).—Mittra (Medical Reporter, January, 1894, p. 12) uses the juice internally, usually in doses of ten drops. He thinks "its action on the stomach as a gastric sedative of great power is seen in the magical relief which it gives in certain forms of gastric irritation and vomiting." As an antacid it is also of much value, even more reliable thus used than is bicarbonate of sodium. Locally applied it has a marked "solvent" action on polypi, warts, small tumors, etc.

Change of Address.—Dr. Emory Lanphear, from Kansas City to St. Louis.

0.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Five Weeks ending May 26, 1894:

MURRAY, R. D., Surgeon. To proceed to Brunswick, Ga., for special duty. April 30, 1894. To proceed to Waynesville, Ga., as inspector. May 17, 1894.

HUTTON, W. H. H., Surgeon. Detailed for duty as inspector of quarantine stations. April 27, 1894.

Hamilton, J. B., Surgeon. Granted leave of absence for three days. May 14, 1894.

Gassaway, J. M., Surgeon. Granted leave of absence for fifteen days. May 12, 1894. Leave of absence extended five days. May 26, 1894.

STONER, G. W., Surgeon. To inspect Cape Charles Quarantine Station monthly. April 27, 1894. Granted leave of absence for thirty days. May 18, 1894. GODFREY, JOHN, Surgeon. To represent the service at meeting of American Medical Association at San Francisco, Cal. May 11, 1894.

IRWIN, FAIRFAX, Surgeon. To proceed to Berlin, Germany, for special duty. May 5, 1894.

Carter, H. R., Surgeon. Granted leave of absence for three days. May 3, 1894. To proceed to Key West Quarantine for temporary duty. May 4, 1894.

Banks, C. E., Passed Assistant Surgeon. Granted leave of absence for five days. May 1, 1894.

CARMICHAEL, D. A., Passed Assistant Surgeon. To proceed to St. Louis, Mo., for temporary duty. May 15, 1894.

PECKHAM, C. T., Passed Assistant Surgeon. To proceed to San Francisco Quarantine Station for duty. May 17, 1894.

GLENNAN, A. H., Passed Assistant Surgeon. To proceed to Wilmington, Del., for special temporary duty. April 25, 1894.

WHITE, J. H., Passed Assistant Surgeon. To inspect quarantine stations. April 27, 1894. Granted leave of absence for seven days. April 29, 1894. Granted leave of absence for twenty-three days. May 4, 1894.

Bratton, W. D., Passed Assistant Surgeon. To report at Bureau, and then to proceed to Delaware Breakwater Quarantine for duty. May 19, 1894.

MAGRUDER, G. M., Passed Assistant Surgeon. To proceed to Key West Quarantine Station for duty. May 15, 1894.

KINYOUN, J. J., Passed Assistant Surgeon. To proceed to Wilmington, Del., for special temporary duty. April 26, 1894. Detailed as chairman Board for Physical Examination Officer Revenue-Marine Service. April 30, 1894. Detailed to attend annual meeting State Board of Health of North Carolina. May 11, 1894. To inspect property at Wilmington, N. C. May 14, 1894.

WOODWARD, R. M., Passed Assistant Surgeon. To proceed to Chicago, Ill., for special duty. May 7, 1894.

VAUGHAN, G. T., Passed Assistant Surgeon. Detailed as recorder Board for Physical Examination Officer Revenue-Marine Service. April 30, 1894.

STONER, J. B., Passed Assistant Surgeon. To inspect quarantine ports. April 26, 1894.

Perry, J. C., Passed Assistant Surgeon. To assume command of service at Norfolk, Va. May 4, 1894.

Young, G. B., Assistant Surgeon. To proceed to Key West, Fla., for duty. May 15, 1894.

Brown, B. W., Assistant Surgeon. To proceed to Pittsburgh, Pa., for duty. April 27, 1894.

ROSENAU, M. J., Assistant Surgeon. To proceed to Boston, Mass., for duty. April 23, 1894.

COFER, L. E., Assistant Surgeon. To proceed to San Diego, Cal., as inspector, and to assume command of the service after June 30th. April 26, 1894.

EAGER, J. M., Assistant Surgeon. To proceed to New Orleans, La., for duty. May 16, 1894.

Nydegger, J. A., Assistant Surgeon. To proceed to Savannah, Ga., for duty. April 28, 1894.

STRAYER, EDGAR, Assistant Surgeon. To report for duty on Revenue Bark Chase. April 28, 1894.

OAKLEY, J. H., Assistant Surgeon. To rejoin station, San Francisco, Cal. May 16, 1894.

#### Promotions.

Assistant Surgeon G. B. Young, commissioned as Passed Assistant Surgeon. May 25, 1894.

Assistant Surgeon W. G. Stimpson, commissioned as Passed Assistant Surgeon. May 25, 1894.

#### Appointments.

ARTHUR R. Thomas, of Illinois, commissioned as Assistant Surgeon. May 25, 1894.

HENRY W. WICKES, of Maryland, commissioned as Assistant Surgeon. May 25, 1894.

HUGH S. CUMMING, of Virginia, commissioned as Assistant Surgeon. May 25, 1894.

#### Society Meetings for the Coming Week:

Monday, June 11th: New York Academy of Medicine (Section in General Surgery); Alumni Association of the College of Physicians and Surgeons, New York (annual); New York Academy of Sciences (Section in Chemistry and Technology); New York Medico-historical Society (private); New York Ophthalmological Society (private); Lenox Medical and Surgical Society, New York (private); Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

TUESDAY, June 12th: New York Academy of Medicine (Section in Genito-urinary Surgery); Delaware State Medical Society (first day-Lewes); Massachusetts Medical Society (first day -Boston); New York Medical Union (private); Kings County, N. Y., Medical Association; Medical Societies of the Counties of Chemung (annual-Elmira), Chenango (semiannual), Delaware (annual), Erie (semi-annual-Buffalo), Genesee (annual-Batavia), Livingston (annual), Onondaga (annual-Syracuse), Oswego (annual-Mexico), Rensselaer, St. Lawrence (semi-annual), Schenectady (semi-annual-Schenectady), Steuben (annual-Bath), Warren (annual-Lake George), and Wyoming (Warsaw), N. Y.; Newark, N. J., and Trenton, N. J. (private), Medical Associations; Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Northwestern Medical Society of Philadelphia; Baltimore Gynæcological and Obstetrical Society; Practitioners' Club, Richmond, Ky.

Wednesday, June 13th: Kentucky State Medical Society (first day—Shelbyville); South Dakota State Medical Society (first day—Huron); Maine Medical Association (first day—Portland); Delaware State Medical Society (second day); Massachusetts Medical Society (second day); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Metropolitan Medical Society, New York (private); Medical Societies of the Counties of Albany, Cortlandt (annual), Dutchess (semi-annual—Poughkeepsie), and Montgomery (annual—Fonda), N. Y.; Philadelphia County Medical Society; Middlesex, N. J., County Medical Society (annual).

Thursday, June 14th: Kentucky State Medical Society (second day); South Dakota State Medical Society (second day); Maine Medical Association (second day); New York Academy of Medicine (Section in Pædiatrics); Society of Medical Jurisprudence and State Medicine, New York; New York Laryngological Society; Medical Society of the County of Cayuga (annual); Brooklyn Pathological Society; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, June 15th: South Dakota State Medical Society (third day); Maine Medical Association (third day); New York Academy of Medicine (Section in Orthopædic Surgery); Baltimore Clinical Society; Chicago Gynæcological Society.

SATURDAY, June 16th: Clinical Society of the New York Postgraduate Medical School and Hospital.

### Obituaries.

#### SAMUEL T. HUBBARD, M. D.

Dr. Hubbard died at his home, No. 27 West Ninth Street, on Friday afternoon. He was born in 1808. He received his early education at the Garfield High School, Middletown, Conn., and at the Suffield Academy. In 1832 he began the study of medicine in New York in the office of Dr. Miller, a well-known physician of the time. He was graduated from the College of Physicians and Surgeons in 1835. Dr. Hubbard was always interested in all that pertained to the welfare and elevation of the profession. He became a member of the Medical Society of the County of New York in 1839, and was its president in 1866.

In 1844 he was elected a member of the Society for the Relief of the Widows and Orphans of Medical Men, and to this organization he always gave the assistance of his counsel and aided it with much needed financial support. He was one of the original members, of which only six survive, of the Academy of Medicine, founded in 1847; its secretary from 1853 to 1858; a trustee from 1859 to 1863, and again from 1872 to 1885, and a vice-president from 1873 to 1876. As one of the committee on ways and means, appointed in 1866, he was most active in raising funds, and the acquisition of the permanent home for the Academy in Thirty-first Street was very largely due to his personal efforts. He was attending and subsequently consulting physician to the Presbyterian Hospital. He was also a member of the New York County Medical Association and the Physicians' Mutual Aid Association. He was an active member of the New England Society.

As one of the typical family physicians for a long period of years, Dr. Hubbard was respected for his medical ability and loved for his kindness to the members of his profession, and his counsel was sought for in all the measures for the honor and dignity of the profession. His wise counsel had much to do with the shaping of the policy of the College of Physicians and Surgeons, of which for many years he was one of the trustees. In private life he was a warm friend, in his family a devoted husband and father, in public affairs honorable and dignified, enjoying the respect of all who came in contact with him. He was a good and true man.

# Retters to the Editor.

INDECENCY IN PHOTOGRAPHY.

Baltimore, June 1, 1894.

To the Editor of the New York Medical Journal:

Sm: Whether photographic illustrations of anatomical and surgical phenomena exhibited by the human body convey as clear and instructive ideas of the conditions worthy of attention as may be conveyed by outline illustrations and drawings may well be doubted.

Photographs of the human tissues are apt to be lacking in "relief" as concerns important points in the field, and so to be confusing. But if photographs of the human body and tissues are to be employed, does not decency require that, even in medical publications, the scope of the photograph should be confined to the parts in which the phenomenon noted occurs; that the rest of the body, being unnecessary to the demonstration, be left out of the field, or be suitably covered up?

This plea is based, not on grounds of morality, but upon that sentiment which is ingrained in all truly refined characters, which medical education and practice need not obscure, the sentiment which is called "decency." Necessary exposure of the human body to the gaze of the physician and surgeon is not incompatible with this sentiment; but the element of necessity must always be kept in view. Modern obstetrics, for example, teaches that the safety of the patient demands free exposure of the obstetric region; but it demands that other regions be kept properly covered. Modern gynæcology gives the same right and exacts the same limitations. Are not physicians and surgeons guilty of indecency, if in photography they transgress these limitations? Is it not time that protest should be entered in the medical press and by medical men against ruthless license in such photographic illustrations?

There is a personal flavor about the photograph which is absent in the drawing or the outline, since in these latter forms of representation only the regions necessary to explanation of the facts described need be faithful to the model. Each of these photographic illustrations, however, with which modern articles on obstetrics and gynæcology abound represents some particular woman who has been photographed (we may well believe, while unconscious under anæsthesia and without the consent of herself or her friends) while placed in the humiliating back or knee-elbow position, which might just as well be described in words or in outlines, for the performance of an examination or operation which in many cases could be better explained by a careful use of the English language and by diagrams. In many of the most repulsive photographic illustrations we can, after careful study, find absolutely no point in which they throw valuable light on the printed description.

The question arises, even in the most generous mind, Is this indecent exhibition not prompted by a desire of the operator to advertise himself and his school, especially when he includes his antiseptic furniture and his own features? If this is the motive, is it not time to call a halt? Have not the profession a right to object, and to object loudly and persistently, against such unnecessary liberties with patients whom they have recommended to the care of the operator? Even in dealing with poor and friendless patients, is it desirable that the surgeon who aspires to greatness should violate the natural instincts of civilized man?

My plea is on behalf of decency. I have taken the lowest possible ground of controversy; but is there not a meanness in thus taking unnecessary liberties with the unconscious patient who has confided herself to one's professional care? Is there not indication here of a lack of moral tone which is unworthy of teachers in institutions of good repute called to form the characters of future physicians?

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Third Triennial Meeting, held in Washington on Tuesday, Wednesday, Thursday, and Friday, May 29, 30, and 31, and June 1, 1894.

The President, Dr. Alfred L. Loomis, of New York, in the Chair.

(Continued from page 694.)

500

Chemical, Physical, and Bacteriological Studies upon Air over Decomposing Substances, with Special Reference to their Application to the Air of Sewers, was the title of a

paper with which Dr. Alexander C. Abbott, of Philadelphia, opened a general discussion of the subject of Sewer Gas in the first part of the second day's session, which was under the direction of the American Climatological Association. Dr. Abbott said that under ordinary circumstances the difference between the chemical composition of the air from sewers and that of the atmosphere outside was very slight, and that, contrary to general opinion, there were comparatively few bacteria. It was also very commonly but erroneously supposed that sewer gas was under very decided pressure. Professor Chandler had collected abundant evidence to the contrary. There was, moreover, not a single conclusive demonstration that the air of sewers stood in an ætiological relation to many diseases for which it was popularly supposed to be accountable. The fact that the air in sewers was not under pressure, as a result of decomposition of the sewage, together with the fact that sewers were far from being air-tight, showed that the air of sewers was not likely to be driven out of the sewers under any great pressure.

But little was known as yet regarding the nature of the bacteria found in the air of sewers. Experiments had been made at the laboratory under his direction with a view to determining the effect of the breaking of gas bubbles on the conveyance of micro-organisms through the air. After endeavoring to simulate the natural conditions, it was found that such bubbling had but little influence of this kind. Bubbling was not a frequent condition in sewers, and, even should it occur, it was hardly conceivable that this would result in the transfer of micro-organisms from the sewer through the various branches and pipes leading to the houses. Then, again, if many pathogenic bacteria were present in the air from the sewers, those who worked in the sewers would show it in the effect on their health.

The Effect of Sewer Gas on the Production of Disease was the title of the next paper, by Dr. Abraham Jacob, of New York. The atmosphere, he said, was a favorable medium for germs. They tended, however, to fall to a low level, and hence might often be breathed by little children when taller persons would escape them altogether. The force of evaporation was not sufficient to lift the smallest micro-organisms from a moist surface, and consequently they could only gain access to houses by the action of an exceedingly strong draft of air, and not usually then.

Dr. Andrew H. Smith had told him of an interesting series of cases of amygdalitis which had occurred in St. Luke's Hospital, New York, and had been promptly arrested on the substitution of an iron pipe for a defective brick sewer. Another series of observations of great importance had been undertaken under the direction of Dr. Hermann M. Biggs, of the New York City Board of Health. A thousand cases of pseudo-diphtheria occurring in New York from August 1, 1893, to April 1st of the present year had been carefully mapped out and studied, and it had been found that the spread of affections of the throat, especially diphtheria, was not at all related to a defective condition of the sewers. Diarrheal disease had not been diminished by improvement in the construction of the sewers. The large number of cases of typhoid fever occurring in New York city every fall were explained, in his opinion, by large importations of the disease with the annual return of the people from the summer resorts.

The speaker then reported a case which he believed illustrated the occurrence of direct cesspool poisoning. He stated also that he had seen typhoid fever and outbreaks of dysentery occur in tenements where the water-closets were not in proper condition. Of all the medical testimony on the subject under discussion, perhaps the best was that given by Dr. Louis Fischer,

in an article published in the Medical Record for January 28, 1893. Dr Fischer had endeavored to show that diphtheria sometimes spread from floor to floor in tenements, following the line of the waste-pipes, and wholly avoiding families living on the opposite side of the house. In about thirty per cent. of his cases, pathogenic bacteria were found. This, however, only proved that such germs were ubiquitous. Of the specific germs, those of typhoid fever and dysentery appeared to be the least easily destroyed of all the micro-organisms found in sewers.

Sewer Gas as a Cause of Throat Disease.—Dr. Beverley Robinson, of New York, continued the discussion with a paper thus entitled. He thought it was a demonstrated fact that persons ill with diphtheria became more severely ill if compelled to inhale the air from sewers continually. In his opinion, if a person with catarrh of the throat and a tendency to inflammation of these parts was exposed to sewer gas, he would be liable to have an attack of inflammation. This he had seen time and again.

The house physician of the Willard Parker Hospital had recently informed him that, notwithstanding the large number of cases of diphtheria in that hospital, they had not been able to find the Loeffler bacilli in the air about the patients. It had recently been shown that many of the children in the Hospital for the Ruptured and Crippled had been going around the wards with the Loeffler bacilli in their throats, without showing any symptoms of diphtheria.

Dr. William H. Welch, of Baltimore, said that he had been agreeably surprised at the valuable additions which had been made to our knowledge of this vague subject by the present discussion. This was particularly true of the observations of Dr. Abbott and the statements made concerning the investigations of the New York Board of Health. The latter observations seemed to show that even diphtheria had no connection with the emanations from sewers. This left but little except the very vague and nameless condition ordinarily referred to by physicians as "sewer-gas poisoning."

The Distribution and Control of Leprosy in North America.—The second half of the session was devoted to a discussion on Leprosy, and was in charge of the American Dermatological Association. Dr. J. NEVINS HYDE, of Chicago, opened the discussion. He said the fact that leprosy had not spread over the United States was due chiefly to the excellent habits of our people. It was far more prevalent in the southern portion of the hemisphere. The United States enjoyed the unenviable distinction of allowing its lepers to go whither they would in Pullman cars over the whole length and breadth of the country. The American Dermatological Association had been the first to take steps toward securing statistics regarding leprosy in the United States. It was calculated that there were very nearly a hundred lepers in this country at the present time. These facts should call forth an earnest discussion, and lead to provision both for the leper and for the people in general.

The Distribution and Control of Leprosy in North America.—Dr. James C. White, of Boston, continuing the discussion, said that the history of its introduction and extraordinarily rapid spread in the Hawaiian Islands could only be explained by infection from person to person. It was very difficult to prove its direct communicability, as its period of incubation might vary from two to ten years. The well-known case of Father Damien was alone sufficient evidence of its contagions nature. It was a disease bearing a striking resemblance to syphilis and tuberculosis. In past ages the leper had been so rigorously isolated, and the disease in this way checked, that both physicians and the laity had come to doubt if leprosy were really contagions.

The discovery by Nansen of the Bacillus lepræ demonstrated its contagious character as clearly as the discovery of Koch proved the same proposition in regard to tuberculosis. The bacillus of leprosy was found in great abundance in the blood and widely scattered throughout the organs and secretions of the body. In Norway and Sweden there had at one time been no restrictive regulations regarding lepers, but the government had at last changed its policy in this matter, and as the result of such legislation the number of cases of leprosy had been reduced in Norway from 2,607 in 1870 to 800 in 1893.

In conclusion, the author recommended that every physician should be compelled to report every case of leprosy to the nearest board of health; that immigrant lepers should be prevented from entering this country; and that graded hospitals should be established by the national government for the proper care and isolation of lepers.

Dr. George H. Fox, of New York, said that, although leprosy must be considered as communicable, the danger of infection of those associating with lepers was extremely slight For over a generation there had been cases of leprosy in New York State, both inside and outside of hospitals, and yet no case of direct infection had been observed. In his opinion, a case of syphilis was a hundredfold more liable to spread disease through a community than a case of leprosy. He could recall the case of a college professor who, instead of being the unhappy creature that a leper was usually pictured to be, had been able to carry on his work, and that too without many discovering even the existence of the disease. A leper was no more a menace to the public health than the victim of pulmonary tuberculosis. It seemed to him inconsistent to demand legislative protection against lepers because they were few, while we went on allowing syphilities and consumptives to increase and multiply in every part of our country.

Dr. Joseph D. Bryant, of New York, said that enough was already known of leprosy and of its victims to justify the taking of prompt steps for its extermination. If this disease should smite this country as it had smitten the Old World in the eleventh century, then indeed would abject fear take the place of pity and dread. At present lepers were really outcasts, and were subjected both to public and private persecution, and hence national legislation to insure segregation of lepers was certainly humane from every point of view.

Dr. Walter C. Wyman, of the Marine-Hospital Service, spoke of past and present legislation affecting lepers in this country, and showed that by such restrictions the entrance of these dangerous individuals had been prevented. He also pointed out the difficulties in the way of further legislation, and the probable line of action which would be followed by those who desired to see lepers placed under national control.

Dr. A. Van Harlingen, of Philadelphia, in the course of a few brief remarks on the diagnosis of the affection, stated that he understood that, as a result of the failure of our examiners to detect some of the very early manifestations of leprosy, a large number of lepers from Norway had gained entrance to this country. The most important factor in the treatment was segregation.

(To be continued.)

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

SURGICAL SECTION.

Meeting of April 13, 1894.

Dr. John B. Roberts in the Chair.

A Radical Operation for Congenital Hydrocele in an Adult.—Dr. Thomas S. K. Morton presented a man, aged twenty years, upon whom he had operated six weeks previously for congenital hydrocele of the tunica vaginalis testis. Incision and ligature of the neck of the sac, with subsequent packing with iodoform gauze, had been the method of treatment adopted.

The symptoms were a large fluid distention of the right tunica vaginalis, pain and sense of weight, the disappearance of the fluid during the night and upon prolonged pressure of the scrotum, together with profound melancholy incident to the patient considering himself subject to serious disease of the sexual apparatus.

He had been etherized, and a four-inch incision had been made in the scrotum and sac. A probe could then be passed upward through the patulous but very small calibered unobliterated funicular process into the abdominal cavity. A curved needle armed with strong chromicized catgut had been passed through the tissues surrounding this sinus beneath the tunic, avoiding the vas deferens and spermatic vessels, and brought out at the point of entrance. When the ligature had been tied down tight, an effectual approximation of the neck of the sac at the external ring had been secured, and all communication with the peritoneal cavity cut off. The sac had then been carefully searched for fibrous or other bodies; none being found, the cavity of the tunic had been lightly stuffed with iodoform gauze after its edges had been sewed to the skin margins of the wound by a continuous suture.

The packing had been renewed every two days. In five days he had been able to get up, and at the end of ten days had returned to work, wearing simply a pad of bichloride cotton held in place by a suspensory bandage. The wound had finally closed, under stimulation by twenty grains of nitrate-of-silver solution, within three weeks. The result, as demonstrated by the patient to the section, had been perfect, and the man had returned also to a normal mental condition.

Pickaxe Wound of the Brain.—The chairman presented a patient who had recovered from a pickaxe wound of the brain, and said that the man had been brought to him at the Polyclinic Hospital with a small wound of the skull through which the brain substance oozed. He had been struck with a pickaxe shortly before admission to the hospital. Within an hour and a half after the injury he had laid open the skull, and had found pieces of bones driven into the brain. He used the mallet and chisel to cut away the edge of the fracture, and with a forceps removed the fragments of bone from the brain tissue. His finger passed nearly an inch down into the brain structure, which was soft. He had then washed away, with a stream of bichloride solution, the soft brain tissue. As there had been a good deal of oozing from the pia he had stuffed a small piece of gauze into the wound to make a little pressure, sewed up the scalp wound at the ends, but allowed the gauze to stick out at the center. The wound had united by first intention where the edges had been sewed together; and by second intention where the wound had been kept open by the gauze, which had been removed at the end of twenty-four hours. At the present time the wound was healed and the man was well. The pulsation of the brain could be seen where the bony wall was absent. It was four weeks since the accident had occurred. If trephining had not been done Dr. Roberts believed the man would have died of cerebral abscess.

A Misplaced Testicle restored to its Proper Position.— Dr. Edward Martin presented a case of misplaced testicle in a boy aged nine years. He had the testicle normally descended on the left side, but on the right side it had gone into the perineum, lying an inch in front of the anus. It was freely movable and normal in size. The difficulty, of course, had been that from its false position the gland had been exposed to traumatism. The boy had already suffered from one attack of acute orchitis. The history of these cases of misplaced testicle showed that the gland was at first entirely normal in structure and development; but that it finally, simply from chronic inflammation incident to repeated slight injuries and atrophies, had become useless; hence the great importance of shifting the still normal testicle to its proper protected position.

The only method to be considered in this case had been a free incision, division of adhesions, and replacement. The testicle had been cut down upon. The cord had been dissected free; some dense fibrous bands passing backward toward the anus and adherent to the epididymis had been cut, an opening had been made in the tissue of the scrotum, and the testicle had been secured in its proper position by two stitches passing through the lower part of the vaginal tunic and the inner skin surface of the base of the scrotum. The long wound had been united in a cross direction, thus deepening the scrotal sac. The wound had healed without suppuration, and the testicle lay in a perfectly normal position.

The boy was now perfectly well and able to ride a bicycle without discomfort.

Paralysis of Bell's Long Respiratory Nerve.—Dr. MARTIN reported a case of paralysis of the long respiratory nerve following typhoid fever. During the fourth week of convalescence from typhoid fever it had been noticed that the angle of the right scapula had become very prominent. This had been diagnosticated as a dislocation of the scapula—that is, a slipping of the lower angle of the scapula over the fibers of the latissimus dorsi muscle.

On examination it had been at once apparent that the serratus magnus had been palsied. In addition to its respiratory function the serratus magnus was directly concerned in the movements of the shoulder. By its tonic contraction it held the scapula, especially its lower angle, closely applied to the chest, and when thrown into full action rocked this bone outward, thus enabling the arm to be carried upward. The deltoid could lift the arm out and up till it was held at right angles to the long axis of the body; the rocking of the scapula by the serratus carried the arm up. Inability to raise the arm higher than the shoulder had been well marked in this case. Under treatment by massage and electricity the patient had recovered in a great measure. He was not absolutely cured, but the outlook was good, as he believed it was in the majority of these cases of neuritis after typhoid fever. The photographs showed very perfectly both the disability and the wing-like projection of the shoulder blade.

Cured Fracture involving the Atlas and Axis.—Dr. M. H. Cree presented a specimen of which he did not know the history, except that it had been found among a lot of bones when the Philadelphia Dental College had been removed to its present quarters. The atlas and axis were held together by bony union. The odontoid process was not in its normal position, but nearly in the center of the spinal canal of the atlas. From this it would be judged that in the displacement of these bones the transverse ligament had been torn and the patient had lived at least long enough for bony union to take place, although the spinal cord must have been impinged upon to a very great extent.

Non-recurrence of Malignant Mammary Disease after Eighteen Years.—Dr. Thomas G. Morton presented a patient, fifty-six years of age, from whom, eighteen years before, he had removed the right breast for malignant disease; the tumor, a rapidly growing one, had been large and had the usual characteristic symptoms. Since the operation, the patient had had no return of the disease, and continued in excellent health.

(To be concluded.)

# Reports on the Progress of Medicine.

PRACTICAL HYGIENE AND SANITARY SCIENCE.

By CHARLES G. CURRIFR, M. D.

The Model Tenement Houses of London, -- The twentyninth Annual Report of the Trustees of the Peabody Donation Fund shows that on December 31, 1893, there were 19,937 persons of the laboring and artisan class of the London poor resident in 11,273 rooms comprising the 5,070 separate dwellings resulting from the wise management of the very successful and prosperous trust founded by the great Massachusetts philanthropist. These dwellings were arranged so that there were 804 of one room, 2,404 of two rooms, 1,787 of three rooms, and 75 of four rooms. The weekly rent of each ranged from two shillings to seven shillings and sixpence, the average rent of each dwelling being 4s.  $9\frac{1}{4}d$ . a week, and of each room 2s.  $1\frac{3}{4}d$ . This always includes the free use of water, laundries, sculleries, and bathrooms. Like tenements managed by Miss Octavia Hill, as also the various other British improved dwellings for the poor, the Peabody buildings-of which two more blocks, yielding 110 rooms, are at present building in London-should be studied by philanthropists contemplating similar and much-needed hygienic improvements in our cities. While the Peabody tenants are admittedly superior to the average of their class, it is yet of interest to note that the yearly birth-rate among them reached 35.1 in a 1.000 in 1893, being 4.1 in a 1.000 above that of the entire metropolis. The death-rate (including 65 deaths among tenants removed to hospitals) was 17.6 in a 1,000, which is 3.7 below the average of all London for the same period.

The Perils of Football.—In the Lancet, March 24, 1894, pp. 764 to 767, is a list of a portion of the accidents occurring in England from October, 1893, to March 20, 1894. Ten deaths are recorded. The different British football games are considered. It concludes that (1) football is dangerous; (2) contemporary changes have in some respects increased, in some respects lessened, the dangers; (3) probably no modification in the laws (so as to arrest the dangers) would leave the game as good a one as it now is from the athletic point of view. A drastic code is advised, favoring a sweeping and inclusive definition of that growing evil, "professionalism."

Flies as Bearers of Infection (Wiener klin. Woch., March 22, 1894, p. 211).—All observant travelers in Egypt notice an immense amount of eye disease. Blind people abound, and all grades of trachoma and the results of communicable ophthalmia are exceedingly common; from August to November acute ophthalmia is most prevalent. In the conjunctival discharge both gonococci and bacilli occur, occasionally together in the same case. When the bacilli alone are present, the disease is of a milder kind. Besides the familiar causes-extreme filthiness and direct specific contact—an apparent means of dissemination of the disease is found in the myriads of flies which infest Egypt. These remain undisturbed upon the eyelids of children, feeding upon the conjunctival discharge, according to Fuchs, and then transmit the infection further, especially in the warm weather. Lucian Howe found that if such flies were allowed to walk over the surface of nutrient gelatin, bacteria developed wherever their feet had gone. Hirschberg and some other physicians doubt that the flies are in any way the carriers of the infection. Yet the Bedouins of the desert regions, where there are comparatively very few flies, present a smaller proportion of eye

Sunlight as a Disinfectant is studied by E. von Esmarch in Zeitschrift für Hygiene, etc., xvi, ii (1894), p. 257. The gen-

eral value of sunlight in this regard has been extensively assumed and advised for disinfecting leather, delicate furniture coverings, furs, etc. Boubnoff has shown (Archiv f. Hygiene, x, p. 335) that the recognized beneficent action is not simply superficial, but that its chemically potent rays can exercise an influence quite through a fabric of ordinary thickness. Cholera germs, even on and in deeper layers of tissues experimented with, die very promptly under the influence of sunlight, none surviving for an hour. This is explained by the familiar fact that mere drying is sufficient to kill these. Esmarch found that dark fabrics prevented the bactericidal action of the sun's rays upon infected fabrics underneath much more than did lightcolored cloth. So the sun's warmth could not have been a very important factor in producing the results obtained. It was found that even the simplest linen covering, upon cushions and pillows, protects from destruction such disease germs as are not sensitive to drying. Although, in one of the several experiments with diphtheria bacilli, an exposure to sunlight for five hours killed all of the bacilli to the depth of three thicknesses of cloth (infected from cultures), in other cases twenty hours (of sunlight on successive days) did not suffice to kill them when inside of cushions or pillows. In the depths of the wool of a sheepskin thirty-nine hours of actual unclouded sunshine failed to destroy the vitality of the bacilli of diphtheria. For mattresses, cushioned furniture, etc., the unaided influence of sunlight is unreliable where disinfection is absolutely necessary. Steaming is to be employed, if practicable, as being by far the best means. Otherwise, a liberal use of a five-per-cent, solution of carbolic acid is needed. Esmarch concludes that mere sunlight in our latitude affords only an unsatisfactory and usually quite inadequate means of disinfecting infected objects, with the probable exception of articles from cholera cases, as above indicated. Other observers are not disposed to accept these results. Karlinski, an expert bacteriologist (Wiener med, Woch., Feb. 17, 1894), escorted a band of pilgrims and made a number of interesting observations in connection with two hundred and ninety-two examinations of cholera dejecta. The vibrio (comma bacillus) was at times very difficult of recognition and was in a few cases present without causing cholera symptoms. While at El Tor, he made a few experiments and reached the conclusion that the sun exerted an important influence as a disinfector, and that not merely because of its warmth and drying power.

Practical Disinfection of Infected Railway Cars.—Petri and others (Arbeiten a. d. kais. Gesundheitsamte, ix, i, p. 111) inoculated one hundred and seventeen guinea-pigs with car dust. After from four to six weeks all of these animals then living were killed and examined for tuberculosis. Three positive cases of the disease were found among all these animals thus treated. These three cases came in the guinea-pigs after they were inoculated with the dust from two sleeping cars. Of the other one hundred and fourteen, infectious diseases killed forty-five, as follows: Twenty-seven died from peritonitis, fourteen from malignant ædema, two from abscess of the liver, one from abscess of the abdominal wall, and one from tetanus. Floors of cars were examined three hundred and eighty three times, and 42.6 per cent. of these were found to have sputa present in notable amount. From thirty-four of the worst soiled, ninety-one guinea-pigs were inoculated. Of these, 30.8 per cent. died in consequence. The remaining sixty-three animals were killed in six weeks. All were healthy except three, which were found to have acquired tuberculosis. Among the seven kinds of bacteria found in the sixty-three guinea-pigs (killed), the pyogenic staphylococcus and streptococcus were the most conspicuous For disinfecting cushioned, carpeted, and otherwise upholstered cars, steaming is the only absolutely reliable method. For wooden seats, box cars, and woodwork in general, washing and scrubbing with brush and warm two-and-a-half-per-cent, solution of soft soap, and subsequent rubbing dry, reduced the number of bacteria present to less than one per cent, of their original amount. A stream of water from a loose, as also a spray or sprinkled jet of water, did not remove more than seventy per cent. of the bacteria present. Subsequent rubbing cleansed much more effectively. A 1-to-1,000 solution of corrosive sublimate, soaking the wood for four minutes, destroyed nineteen twentieths of the bacteria, but not the tubercle bacilli. Fresh oil paint applied over an old painted, infected wood surface, left it sterile.

The Practical Management of Gravity Sand Filters is discussed by Piefke, engineer of the Berlin Waterworks (Zeitschrift für Ilygiene, February, 1894, p. 151). When many green algæ are in the unfiltered water, they quickly obstruct the flow and necessitate cleansing of the surface before forty cubic feet of water have passed through each square foot of sand surface. Tests of both filtered and unfiltered water by means of the gelatin-plate method should be made once daily. It is best that every filter bed be separately tested. The fairest time to do this is after a filter has been working steadily for some hours. The pressure must not exceed four feet of water above sand surface. The velocity of flow should not exceed four inches an hour. The filter is apt to work defectively—

1. If there is no adequate provision for accurately regulating the flow. (Irregular flow prevents good results.)

2. If there is too high pressure.

3. If the fine sand layer on top is not kept thick enough.

4. If sedimental coating (to secure mechanical holding back of bacteria) is lacking.

Silt affords an excellent sediment for filter beds. Iron oxyhydrate comes next, and is more efficient than algæ. When algæ are relied upon for this film-formation they settle more promptly if abundant light is furnished.

A formula of efficiency (E) is given:

F 7 7

$$E = \frac{R}{v_m \times p_m}$$

where  $v_m =$  mean velocity;  $p_m =$  mean pressure. R = retentive capacity of the upper layer of the filter bed. This element (R) is much weakened just after a cleansing of the surface. Hence the velocity must be very small at the beginning of use after cleansing. Later, it can be increased. With the strengthening of R the pressure can be increased, yet not very much. It is important to note that the quality of the element R necessarily varies with the locality, because of the varying character of the sedimental constituents of the unfiltered water.

Sewage Disposal is a problem of growing importance. Sewage farms are unprofitable unless under very favorable conditions. The Sanitary Record (March 3, 1894) illustrates this by citing the admirably conducted Birmingham (England) farm of four hundred acres which is carried on at a yearly loss of £30,000. Two fifths of this loss is on the working of the farm and three fifths represents interest on the capital invested. The two special causes of this unprofitableness are: 1. The necessity of using eleven tons of lime daily to neutralize the unusual acidity of the sewage. 2. There is insufficient fall for the sewage. Hence settling tanks and dredges have to be provided. Sewage purification by chemical precipitation is carried on in Worcester, Mass., on a larger scale than anywhere else in this country. The city engineer's report shows that the peculiar situation makes this process desirable although rather costly. Since the sewage intermittingly contains much iron in an acid solution, that is utilized instead of alum. To each million gallons of sewage about one thousand pounds of lime are also added. About half of the total volatile residue and of the al-

buminoid ammonia are removed by the treatment, which also lessens the bacteria by ninety-three per cent. The embarrassing question of the utilization of the sludge is not settled. Here, as in Europe, farmers are loath to employ it as manure, for it has only half the fertilizing value of horse manure. Cremation of sludge is effectual, as was demonstrated at the Columbian Fair. The "electrozone" method of purifying sewage or sewage-contaminated water consists in the addition of common salt (if enough is not already present), and then liberating chlorine from this solution by the use of an electric current. It is simply a proprietary method, and apparently a rather expensive one, of producing a solution of sodium hypochlorite (chlorinated soda). In the (preliminary) Report of the New York City Health Department for 1892, published in the City Record Supplement of February 3, 1894, there are given (on page 35) the reports of several experiments which serve to corroborate the previous observations of various European biologists and of Dr. Duggan (see the 1885 Report of the American Public Health Association) to the effect that chlorinated soda and chlorinated lime are valuable disinfectants by reason of their active chlorine. For the privilege of using this proprietary process, or the similar European one known as the Hermite process, the mere royalty charged appears to amount to as much as the necessary amount of fresh sodium or calcium salts of hypochlorous acid. Of these, chlorinated lime is to be preferred in most cases if the following is corroborated by further tests. It will be interesting to observe the results at Danbury, Conn., where, according to the Engineering News, the proprietary method is to be tried. Chlorinated lime is said by Traube (Zeitschrift für Hygiene, etc., February 8, 1894) to kill within two hours all micro-organisms in, for instance, one wine quart (litre) of water (containing many bacteria), if to this amount of the unwholesome water 0.00426 gramme of the fresh calcium salt is added, containing 0.001065 gramme of available chlorine. Less than ten per cent. of the chlorine was used up in the experiments. To neutralize the unused chloride of lime the subsequent addition of 0.00209 gramme of sulphite of sodium (as an efficient "antichlorine") is therefore advisable after the chlorine compound has done its work. An excess of fifty per cent. of this sodium sulphite is not objectionable, for within fourteen hours the excess is oxidized by the free oxygen of the water to wholly indifferent sodium salts. After this treatment the water is said to have an excellent taste, and it is rendered only about one (English) degree harder than before the calcium salt was added.

[If careful and repeated experiments with American sewage show that the small quantity of chemicals indicated in the preceding paragraph suffices to sterilize all disease germs and fæcal bacteria of sewage, the process is certainly to be recommended as quite inexpensive. According to Klein, of London, and Pfeiffer, of Wiesbaden, much larger quantities are needed. The reporter proposes to test the efficacy of these small amounts of chemicals upon the sewage of certain of our cities. The above figures require a trifle less than forty pounds of fresh chlorinated lime and nearly eighteen pounds of sodium sulphite for one million gallons of sewage! The bisulphite of sodium is the most available "antichlorine" sold here, and in barrels containing somewhat more than five hundred pounds sells in New York city for two cents and a half a pound. The same price is charged for the calcium salt ("English bleach") in casks. Small packages cost more by the pound.

The Contamination of Well Water by Leakage from Privy Vaults, etc., can be detected—as is well known—by adding lithium salts to the contents of the vault and afterward testing neighboring wells, first evaporating a considerable quantity of the water and then employing the spectroscope. A much easier and quite reliable means is the careful addition of the

approved disinfectant, saprol, to the vault, manure heap, or other suspected source of contamination (Noerdlinger, ref. in Ges. Ingenieur, April 30, 1894). The ordinary commercial article is used, containing forty per cent. of cresol. If contaminated from a vault to which this is added, water will soon betray the presence of this coal-tar product, for it is easy, by the sense of smell, to recognize one part of saprol in a million parts of water. To the sense of taste it is twice as evident. That is, the characteristic taste—reminding one of illuminating gas or naphthaline—is very marked when saprol is present in the proportion of only one part in two million parts of water.

A Rapid-culture Method for Recognizing Cholera Vibrios in Fæces is strongly recommended by Maasen (Arbeiten aus d. kais. Gesundheitsamte, 1894, p. 122). It consists in the use of tubes of sterile, coagulated blood serum. Small portions of shreds and of soft masses from the intestinal contents or dejections are (by a sterile looped wire, glass rod, or other means) spread out upon several of the serum surfaces. They are kept in a thermostat for from six to twelve hours. Cholera vibrios, if present, will then have caused erosions of the surface as though the coagulated serum had been gnawed out. In the depths of the holes and grooves the vibrios can be found in almost pure culture. This culture medium is advisable as a secondary (and confirmatory) test where the peptone-salt method has been used with suspected water. The serum method is preferable to the usual peptone-water method because (1) more disease matter can be used; (2) if the serum is fluidified within twenty-four hours the probability at least of the presence of cholera germs is great, even without a microscopic examination of the culture; (3) if the serum shows none of the above indicated change, no cholera germs are present; (4) within twentyfour hours other bacteria will not have developed so much as is the case where fluid culture media are used. A modified Uschinski culture method of rapidly detecting cholera vibrios is given in the Centralblat für Bakteriologie for April 7, 1894, p. 456.

Egg Albumin as a Culture Medium for Detecting Cholera Vibrios in from five to ten hours (of thermostat) is emphatically recommended by Zabolotny (Deutsche Med. Woch., Dec. 21, 1893). This medium causes cholera colonies to develop with characteristic appearances similar to the typical colonies produced upon gelatin. To keep the coagulated albumin transparent, it is prepared with the addition of not much more than forty per cent. of water and sixty per cent. or less of a one-percent. solution of caustic potash or soda. For sterilization, a temperature several degrees below 212° F. is used. The details of preparation are to be found in Biologisches Centralblatt, 1888, pp. 307-311; also in late editions of Hueppe's text-book and in bacteriological journals for 1888. Freymuth and Lickfett recommend plate cultures made on a compound of agar (twelve parts), gelatin (thirty parts), glycerin (twelve parts), and Koch's bouillon (nine hundred parts). This develops colonies in six hours of thermostat (temperature, 98.5° F.). Another method of employing egg albumin for cultures is given by Wesener in Centralblatt für allg. Pathologie, January 31, 1894. The egg is shaken and boiled, and slices of the mixed albumin are used for cultures.

Surface Cultures of Typhoid, Cholera, and Other Disease Bacteria can be most successfully produced upon nutrient getatin and other solid culture media by using a clean, sterilized camel's-hair brush for spreading the containing water, blood, or secretion. Thereby, according to Kruse (Centralblatt für Bakteriologie, etc., March 24, 1894) the usual distinctive, aerobic, surface colonies develop more promptly and certainly than when gelatin plates are prepared in the usual (or any other) manner.

Typhus Fever.—Dubief and Bruhl (in Archives de médecine expérimentale, etc., March 1, 1894, pp. 224-249) consider this as a disease whose chief lesions are located in the throat and respiratory tract. It is a localized infection whose toxic products invade the system and thus produce the stupor, dilatations of vessels, and other symptoms. In the lesions Dubief and Bruhl find a presumably causative diplococcus, developing best at a temperature of about 104° F., liquefying gelatin slowly, readily stained by aniline colors, and especially by Gram's method. It seems very resistant to drying, and can remain virulent for months when dried. It is not a pus-producer. It would appear that it is chiefly by means of expectorated products of this disease that the infection is diffused.

Typhoid Bacilli.-Various experts in America and Europe doubt whether these bacilli can be differentiated from certain other varieties that are harmless although they very closely resemble the genuine ones. Yet new tests, considered absolutely reliable and conclusive by their originators, are announced every few months. Schild (Zeitschrift für Hygiene, etc., March 2, 1894, p. 378) strongly recommends the addition of 1000 part of formalin to culture bouillon (and gelatin) after steril ization. Formalin is a forty-per-cent. aqueous solution of formaldehyde. It is one of the newer proprietary disinfectants, is not very stable, and is decomposed by heat. Incorporated into the culture media in the proportion of one part of this to seven thousand of the bouillon (or gelatin), it prevents the growth of typhoid bacilli, allows water bacilli to grow slightly, and permits the Bacterium coli commune to flourish.

Typhoid Bacilli.-Germano and Maurea (ref. in Centralblatt für Bakteriologie, etc., Jan. 16, 1894) have studied these bacteria very fully. They recognize about thirty distinct varieties of typhoid-like bacilli that counterfeit the genuine more or less exactly, and several kinds of these may be found in the same fæcal matter. The term Bacterium coli commune likewise comprehends several varieties. These experimenters do not confirm the opinion of Rodet and Roux that other kinds of bacilli become converted into genuine typhoid bacilli. Nor do they agree with Babes that there are several varieties of typhoid bacilli. Yet they declare that the genuine ones may differ in luxuriance of growth and in degree of virulence. Germano and Maurea find that the potato test fails in certain regions and is therefore not of universal value. While seemingly unfamiliar with Dr. Th. Smith's adaptation of the Kühne fermentation tube (see Wilder Quarter-Century Book, 1893, pp. 225-233, and Thirteenth New York State Board of Health Report, 1893, p. 712) for studying the production of gas in bouillon cultures of bacteria, Germano and Maurea regard the evolution of gas in puncture cultures in agar that contains two per cent. of glucose) as absolutely proving the bacillus not to be typhoid. It is important to have control cultures of the genuine typhoid bacillus at hand for comparison whenever one is testing the character of a doubtful culture.

The Resistance of Typhoid Bacilli against Drying was tested by the late J. Uffelmann (Centralblatt für Bakteriologie, etc., Feb. 5, 1894). His results corroborate the general view that typhoid bacilli withstand drying for a month at least, and in some cases (in dirt, sand, cloth, etc.) they retain their vitality for several months. The possibility of their being carried by air currents and thus conveying infection is assumed, but neither German nor French experimenters who have worked upon this problem have adduced much evidence.

Hydrophobia.—In 1893, at the Pasteur Institute in Paris, there were treated 1,648 persons who had been bitten by rabid animals. Of these people four died unquestionably in spite of the treatment. The mortality, therefore, was at the rate of 2.4 in a thousand, being nearly the same as in 1891 and 1892. Among these were not included four other deaths, because the

treatment was not completed. In 508 of the cases the bite was not unquestionably proved to have been that of a rabid animal. In 1,008 cases hydrophobia of the biting animal was confirmed by veterinary examination. In 132 cases hydrophobia was demonstrated by the development of the disease in untreated animals bitten by or experimentally inoculated with the medulla of the biting animal. Of the 1,648 people treated, 178 came from places outside of France; of these foreigners, one was from Brazil and one from the United States. (Annales de Plastitut Pasteur, March 25, 1894.)

Tuberculosis, and its dangerous communicability among human beings and animals, can no longer be said to be viewed with indifference by the laity, although most of our legislators are at present in favor of a parsimonious policy. Scientific cleanliness on the part of the human sufferers and their attendants is generally inculcated by physicians. That this teaching has produced good results may be inferred from the fact, recorded in the Thirteenth Annual Report of the New York State Board of Health, that in the entire State the proportion of deaths from consumption has almost constantly lessened from 1885, when, out of each 1,000 deaths, 139 76 were due to that disease, while in 1892 the number was 106-66.

Besides the publication of Dr. Salmon and Dr. Smith, in 1892, on Diseases of Cattle and Cattle Feeding, issued by the United States Bureau of Animal Industry, numerous articles have been circulated widely, especially among those having to do with cattle. Of the more recent, as presenting the essential facts in a simple form, are to be recommended the report by Dr. Bryce on Tuberculosis in Ontario (February, 1894), and Bulletin 65 of the Cornell University Agricultural Experiment Station (April, 1894), by Professor James Law (each fifty-one pages). Careful veterinary inspection of slaughtered animals in Europe and in various States of this country shows that less than one per cent. of cattle under one year of age have the disease. After the first year of life the proportion of infected animals increases rapidly. It is reported that upward of forty per cent. of slaughtered cattle over six years of age have tuberculosis. The respiratory organs and their glands are found to be affected in a much greater proportion than the intestines and other abdominal organs. In cattle, as among human beings, infection derived from milk seems insignificant compared with the vast amount of lung tuberculosis due to bacilli borne on dust and diffused through the air of crowded, ill-ventilated, and unclean buildings. In a mild climate, where there is little or no need of housing, there is only slight danger of the infection spreading, even though a case of tuberculosis be present in a herd. Steers that live almost altogether in the open air furnish only one sixtieth the proportion of cases that dairy cows do. The latter, however, have also to undergo the strain of parturition and prolonged lactation, and are thereby rendered somewhat more susceptible.

Skillful auscultation and other physical examination, together with a consideration of the general symptoms, such as cough, dry skin, wasting, etc., are of value in cases where the disease has made considerable progress. Yet beginning and latent cases require other tests. Of these, by far the most prompt and valuable is that afforded by the injection of tuberculin. A small amount of this will have no effect on a healthy horse, pig, or cow, yet feur drops will stimulate into activity the tissues about any tubercles that are present, and, after from eight to fifteen hours, will then cause a notable rise of temperature (2.5° F.). While aggravating the activity of the tubercular process, however slight it may be, in an animal that already has the disease, the employment of tuberculin that is properly prepared is not appreciably harmful for healthy animals. Though objectionable for tuberculous animals that are to be kept alive,

it is indispensable as a means of distinguishing very slight cases so that the disease may be absolutely stamped out of a

Red flesh of tuberculous cattle is not apt to carry the infection. With pork from a tuberculous pig the danger is greater. The blood seems to be quite free from infecting bacilli. With regard to milk, expert opinions differ widely. Some hold that no danger of infection therefrom exists, provided the udder is not obviously diseased; others condemn milk from an animal that is distinctly tuberculous in any organ. The latter seems the safer opinion to be guided by, yet exceedingly few unquestionable cases can be adduced in support of it.

Cooking kills disease germs. None of the bacilli of tuberculosis remain alive in meat or milk exposed in every part to a temperature of 175° F. for more than ten minutes. Yet Professor Law urges that even then the food products coming from a tuberculous animal may contain enough tuberculin to be a source of harm to consumers who have tuberculosis, however slight. The danger seems at any rate quite a minor one.

Professor Law recommends very radical measures in the interest of public health and private welfare, and even as a means of eventual economy to the State.

Private slaughterhouses should be abolished.

Meats, whether fresh or salted and canned, that have not undergone proper government inspection and are not officially declared sound, are to be excluded.

Systematic, skilled inspection of dairy herds and slaughterhouses ought to be under a single administration, and the officials must be entirely independent of private influence.

All farm animals should be examined by skilled veterina-

Old and unthrifty milch cows and all suspected animals are to be isolated; likewise newly purchased cattle until inspected by an expert.

Every tuberculous animal should be killed, and then the carcass (and the manure) destroyed by heat or buried deep enough in a remote place.

No consumptive person should attend to any live stock or prepare their food. Rats, mice, and sparrows in a building where tuberculous animals have lived ought to be exterminated. The premises that have been occupied by tuberculous animals, and especially the articles with which they have been in contact, must be thoroughly disinfected. The results are most satisfactory when this is done at state expense. Illiberality on the part of the state in these matters and lack of thoroughness are poor economy.

Tuberculin and its Value as a Means of Diagnosis in Incipient Tuberculosis in Cattle is considered by Rievel (ref. in Hyg. Rundschau, Feb. 15, 1894). Six heifers were bought for experiment. Of these, three reacted to tuberculin injections, their temperatures being thereby raised by from 1.8° to 4.8° F. These three seemed tuberculous and were therefore slaughtered. Careful expert veterinary examination revealed in two of them acute bronchial catarrh, but neither tubercles nor bacilli. In the third heifer (not the one which showed the highest temperature) a few bacilli were demonstrated in tubercles found in the lymph glands. From these and another similar experience the inference is drawn that tuberculin is not uniformly reliable as an indicator.

Dr. Salmon, Chief of the United States Burcau of Animal Industry, in a letter of April 7th, says: "While the results may not be in every case infallible, it is far ahead of any other means of diagnosis. The number of errors which follow when tuberculin is judiciously used are not sufficient to prove a serious objection to its adoption." [Whoever wishes to study the subject of tuberculin and its exact action, especially as regards

its non-action upon centrally situated tubercles, should read Arthur Klein's Ursachen der Tuberculinwirkung (Vienna, 1893).]

The Sediment of Centrifugal Separators is in some places utilized as food for swine, for it has considerable nutritive value. Ostertag (in Zeitschrift für Fleisch- u. Milch-Hyg., Jg. iv, H. i) advises, however, that such filthy stuff ought to be sterilized if to be fed to swine, since the separating process carries into this sediment most of the tubercle bacilli that may be in the original milk.

Margarine ("oleo" or artificial butter) of pure quality is regarded as equal to genuine butter in digestibility and nutritive value. This view is further corroborated by the results of prolonged and thorough experiments reported at length in recent communications of the Vienna Imperial Academy of Sciences. For the experiments, only pure materials were used for the preparation of the margarine.

## New Inventions, etc.

AN INSTRUMENT FOR EXCLUDING BLOOD FROM THE LAR.
YNX DURING THROAT OR MOUTH OPERATIONS REQUIRING ANAESTHESIA.

BY DWIGHT L. HUBBARD, M. D.

EVERY surgeon who has done severe operations upon the nose, pharynx, or mouth, requiring anæsthesia, knows that they are not without danger. Especially in operations in the pharyngeal vault the operator must work with great rapidity to prevent the blood from doing damage in the larynx and bronchi. This rapid work is not conducive to good results or to a clean operation.

The fact that many different positions of the patient are advised by as many different surgeons is of itself proof that blood in the larynx during these operations is feared. It has seemed to me that if this danger could be obviated, the operation could be done with much greater ease than it is generally done, and the chief danger avoided.

During several years of operating on these cases I have never attempted one under anæsthesia without much anxiety as to the safety of the patient, and always feel relieved when everything is done and the patient has not been asphyxiated by the presence of a blood-clot in the glottis.

When an anæsthetic is required at all in these operations, it is necessary that the anæsthesia be quite profound, for it is only in those cases where a considerable amount of tissue is to be removed that we would consider anæsthesia necessary. The danger of trouble is therefore increased under these circumstances.

I have devised and had made by the W. F. Ford Surgical

Instrument Company a simple instrument, which may be used with perfect ease and which successfully avoids the difficulties mentioned above. It also permits more time for the operation.

It consists of a hard-rubber O'Dwyer intubation tube of any desired size (a set of three is all that is required), to which is attached a hard-rubber tube of the same caliber screwed into the tube by means of a metallic thread. Two slight curves are given to the mouth tube that it may not be in the way of the forceps or curette or other instrument in operations other than for removal of adenoid tissue. The turn to the left permits it to be steadied by an assistant when necessary. The mouth tube acts as the applicator. I do not introduce it until the patient is anæsthetized. The anæsthesia may be kept up through the mouth tube when required for a long operation. I have added for this purpose a little ether cone, similar to that of the Tren delenburg tampon cannula.

The obturator of the O'Dwyer tube has not been found necessary, as the distal end of the tube is made more rounded, taking the place of the obturator. We have, moreover, a normal laryux to deal with, free from membrane.

# Miscellang.

The Anomalies and Complications of Measles .- The Gazette médicale de Paris for May 12th publishes an article on this subject by M. C. Fiessinger, of Oyonnax, who gives his conclusions based on many years' experience with this disease. Contagion, he says, is generally manifested during the period of invasion, and had been direct in all his cases except one. M. Fiessinger has no confidence in Grissole's assertion that dentition aggravates the prognosis of measles. Three circumstances may present themselves: 1. During the normal course of the disease the eruption of a tooth occurs. 2. The rash terminates and the fever persists; bronchitis and diarrhea set in, and these symptoms disappear a short time after the eruption of one or more teeth. 3. The dental eruption is accomplished, but the symptoms become aggravated and death ensues. From this the author concludes that dentition does not influence the prognosis of measles. In three quarters of his cases the eruption had appeared on the third, fourth, or fifth day, but it had sometimes been delayed until the sixth or seventh, and much more rarely until the eighth or ninth. On the other hand, it is sometimes precocious; he has seen it appear on the first day in a child convalescent from endemic influenza. In the author's experience the morbillous exanthem had been seen to develop on the body before attacking the face, and in four cases urticaria had been observed. The urticarial elements had formed white, flat elevations encircled with a red areola; these elevations had appeared on the back, the loins, and the lower limbs before the morbillous exanthem developed and subsided with its appearance. In another case the two eruptions had been simultaneous, the measles attacking the face, while the urticaria spread over the back, the loins, and the thighs for several hours and became rapidly obliterated before the exanthem developed. The urticarial eruption which precedes measles does not, as a general thing, itch very much, and, ordinarily, the temperature does not show any unusual deviation. In two cases only, when the exanthem appeared the fever decreased instead of increasing, and the temperature fell to the normal point.

During the course of the disease hæmorrhages are frequent,

and, in addition to epistaxis, M. Fiessinger had observed hæmoptysis and vomiting of blood, also hæmorrhage from the right ear. Measles is often prolonged by bronchitis; there are moist râles localized at the base and back of the lungs, accompanied by dyspnæa more or less pronounced; diarrhæa sets in with the bronchitis, and fever persists until the temperature has risen to about 102:1° F. The line of demarkation between simple and capillary bronchitis is not very distinct, and during an epidemic, when the physician is pressed for time, he is apt to attach but a slight value to the bronchial signs, and the bronchitis becomes extended, dyspnæa increases, and death follows several days after a favorable prognosis. The stethoscopic signs of morbillous capillary bronchitis often fail to be distinct; moderate dullness on percussion and blowing respiration, indicating congestion or concomitant pulmonary hepatization, may be absent, and the resonance of the lungs remains normal. The reason for this absence of stethoscopic signs depends on one of the two following causes: 1. The lesions are so slight in extent or so profound that they present themselves under the form of focuses so disseminated, or are separated from the thoracic wall by such a thickness of healthy pulmonary tissue, that they are not accessible to the finger or to the ear, and the physical signs do not manifest themselves. 2. The bronchial lesions are really very limited, and the autopsy shows that to them can not reasonably be attributed the dyspnæa and the elevation of temperature observed during life. In this case it is a question of accidents of a toxic order, of a true putrefaction of the blood of which a streptococcus is the habitual agent. Whatever the cause may be, says M. Fiessinger, the physician should be on his guard.

Death from capillary bronchitis or broncho-pneumonia is not always rapid; a fatal termination in pulmonary complications may not take place for several weeks. In the author's experience these two complications had scarcely manifested themselves at the beginning of an epidemic, and seldom in villages where the population was scattered. The former is contagious, as has been demonstrated by M. Bard in an article published in the Lyon médical for January 13, 1889.

Sometimes death seems to be due less to pulmonary lesions than to the intensity of the digestive troubles. Diarrhœa induces a rapid prostration which causes death in the beginning of the disease before the eruption has had time to appear. Again, in some cases where no bronchial or digestive complications had been observed, death was sudden, and could be explained only by the intensity of the disease.

Tracheo-bronchial adenopathy and tuberculous meningitis are the most serious and the most frequent complications. Death from the former had been observed by the author during a period of from several weeks to several months after recovery from the cruptive fever. Pertussis-like coughing set in, the voice became hoarse from compression of the recurrent nerve, there was severe dyspnea accompanied by spasmodic inspiration, and at intervals the attacks caused cyanosis of the face. There was dullness on percussion in front, at the level of the first piece of the sternum. The subcutaneous veins of the antero-superior region of the thorax were very much dilated; emaciation was rapid and loss of appetite complete, and the face became edematous during the last days of life.

...

Tubercuious meningitis is a complication of frequent occurrence, and in a year following an epidemic of measles the number of cases in which this complication sets in is four or five times as great as in an ordinary year. Tuberculosis also invades other tissues than the bronchial ganglia and the meninges. The first signs of Pott's disease had been observed in a child of three years, four months after recovery from measles. Otitis, kerato-conjunctivitis, and ulcers of the cornea, which

may cause loss of sight if they are not attended to, not infrequently follow measles.

Infantile paralysis and acute nephritis, two rare complications, had been observed by M. Fiessinger. The first was in a child of nine months, whose limbs became completely paralyzed a month after recovery from measles; there was also considerable muscular atrophy, with abolition of the tendinous reflexes. Final recovery was effected in two months. The second complication had been observed in a boy ten years old, who became bloated and passed large quantities of albumin. He was kept on a milk diet for fifteen days, after which time the renal lesion was overcome.

One of the most generally discussed complications is the return of the disease itself. The author had observed the case of a little girl who was taken sick a day or two after recovery from the first attack. Coughing and diarrhœa set in, and the exanthem appeared on the face and limbs, and was especially pronounced on the back and the loins. Three days later the eruption disappeared, and at the end of a week recovery was complete.

Ethyl Bromide as an Anæsthetic.—The Gazette médicale de Paris for May 12th contains a report of the proceedings of a meeting of the Académie de médecine at which M. Suarez de Mendoza, of Angers, related the case of a woman who had died suddenly during the first inhalations of ethyl bromide. The death, he said, should be attributed to cardiac syncope, provoked by the action of the vapors of this anæsthetic on the ends of the nasal nerve.

The same journal publishes a paper on the subject of ethyl bromide as an anæsthetic, which was read before the Société de chirurgie by M. Terrier. The author remarks that he has employed ethyl bromide, alone or mixed with chloroform, for a long time, both in the hospital and in his private practice. He had had such variable results from the use of this anæsthetic that he felt it was his duty to analyze several specimens. The public authorities furnished an ethyl bromide that was impure. It was prepared with phosphorus, bromine, and alcohol. The phosphorus employed was impure; it gave out hydrogen phosphide, which caused the alliaceous odor noticed in patients who had been anæsthetized by this method. The ethyl bromide of commerce was prepared with sulphuric acid, ethylic ether, and potassium bromide; this method gave a much purer product. Ethyl bromide contained, then, a large proportion of ethylic ether, and was preferable to that used in the hospitals. The ethyl bromide in common use was not to be compared to the former; the latter contained various substances, and this fact explained the difference in the results. M. Bazy had observed that vomiting rarely followed anæsthesia with ethyl bromide alone, but thought it was not so in "mixed" anæsthesia, as with the latter method, in the case of a child, he had observed abundant vomiting on the patient's return to consciousness.

Antipyrine as a Vesical Anodyne.—In the May number of the Annales des matalies génito-viriaires there is an article on this subject by M. Vigneron, of Marseilles. In regard to the local treatment of inflammation of the bladder, says the author, it is borne quite differently in different cases. When the disease is of moderate intensity, when the application is quite appropriate to the nature of the lesions, when the strength of the solution is not too great, when the method of its application, whether by irrigation or by instillation, has been judiciously selected, and when the temperature of the liquid employed is neither too low nor too high, the patient bears the treatment very well. At the time of the application he feels no pain; at the most, during the first few micturitions there is very slight burning, which diminishes as the applications are repeated.

Unfortunately, there are some persons with whom things do not pass so simply. Searcely is the liquid inside the bladder when it provokes intense pain, ordinarily a sensation of burning, radiating in different directions, and violent contractions of the bladder are produced at the same time, provoking repeated painful and unavoidable acts of micturition, which may in the end be accompanied by the loss of a few drops of blood. The paroxysm lasts for a longer or shorter time, and grows less severe as it is repeated. In persons affected with prostatic disease these contractions may be produced without resulting in the passage of urine, so long as the quantity of liquid contained in the bladder remains below that of the normal residue. Such intolerance rarely persists long if the treatment is well conducted. Most commonly it diminishes after a few days-as soon as the treatment has led to a moderate mitigation in the condition of the lesions. The author has often had proof of this in persons affected with prostatic disease, or with blennorrhagic, calculous, tubercular, or other cystitis. But there are some bladders, he says, in which the depth of the lesions seems to hinder amelioration and tolerance from resulting, and in which the atrocity of the pains would force one to give up local treatment, or at least to come down to the employment of solutions too weak to have any good effect, or to resort to operative procedures. Such was the case with a prostatic patient who declined cystotomy, and the author conceived the idea of employing antipyrine as a vesical anodyne. In two subsequent cases the author has been able to verify its anodyne action, and he mentions Professor Guyon as having used antipyrine for the same purpose. The author gives the clinical histories of three cases, and concludes from an analysis of them that antipyrine may be of great advantage in urinary surgery as a vesical anodyne. The first point that seems to him to be established is that of the perfect harmlessness of antipyrine in the bladder, even when its use is prolonged for months. In spite of very deep and very extensive lesions of the bladder-lesions which increase the absorbent power of the mucous membrane and therefore caused him to avoid the use of cocaine, the dangers of which are but too well known, even in the case of a healthy bladderin the case of the first patient mentioned, no accident was observed as regarded either the skin or the digestive canal, and there was no effect upon the function of the kidneys. There was the same local tolerance. Antipyrine has been employed also, he says, as a hæmostatic by injection into the bladder, and he himself has used it for this purpose, without any effect to be sure, but also without inducing any complications. He has therefore felt warranted in considering it a sufficient antiseptic; experience has warranted him in the opinion that it is equal to boric acid in this respect. As regards its anodyne action, the results are as follows: A solution of antipyrine allowed to remain in the bladder allays painful contractions. This point seems to him settled. From the day when he began to make use of it the first patient could no longer get along without it; twice he tried the use of nitrate of silver followed by that of boric acid, and on both occasions the pain returned. On two occasions the author, in order to assure himself that he was not dealing with a patient susceptible of "suggestion," substituted a solution of boric acid for one of antipyrine without telling the patient, and each time the painful contractions took place as before. When antipyrine is applied only temporarily within the bladder, for the purpose of doing away with the pain which might be provoked by a subsequent application, its anodyne virtue, although not absolutely wanting, is much less decided. If the strength of the solution is feeble (1 to 200), it acts either not at all or only very slightly, and on the condition of being allowed to remain for a very long time-at least twenty minutes -a time much longer than is usually practicable. A stronger

solution (1 to 25) acts sufficiently in ten minutes, more or less decidedly diminishing the pain of an instillation or an irrigation subsequently performed. Antipyrine in solution seems to be indicated as an anodyne in all cases of cystitis in which topical treatment is painful. In cases in which the bladder is not distended one may inject for such a purpose from three to six fluidrachms of a four-per-cent, solution of antipyrine into the bladder about ten minutes before the therapeutic procedure is to be carried out. When the bladder is distended, in order to prolong the procedure indefinitely, one should inject, after the irrigation, from two to four fluidounces of a one-per-cent, or a half-per-cent, solution and leave it in the bladder.

The Early Diagnosis of Cancer of the Cervix Uteri.-The British Medical Journal for May 12th gives a report of an address delivered before the Southeastern Branch of the British Medical Association by Dr. Ernest Herman, of London, in which he says that the early diagnosis of uterine cancer is important, as secondary growths occur later and more seldom with cancer of the uterus than of any other part of the body, and, if it is removed, there is a better prospect of freedom from recurrence than in any other form of the disease. Modern improvements, he says, have made it possible to remove cancer of any part of the uterus, so long as it is limited to this organ, with little risk, but to be successful it must be limited to the uterus. Cancer of the vaginal portion begins in a part that can be felt and seen, and it can be diagnosticated earlier than any other form, and therefore ought to be more successfully treated; cancer of the cervix spreads more rapidly beyond the uterus than the other form, and is less amenable to treatment. This disease occurs chiefly toward the end of the child-bearing period, but it has been seen in childhood and in extreme old age, and therefore the patient's age should not influence the diagnosis in the least. A tendency to cancer is sometimes hereditary, but this should not have the slightest weight, as only a very small proportion of patients inherit the disease.

The first symptoms of cancer are usually hemorrhage and leucorrbœa; pain and wasting come later. The early diagnosis is so important, says Dr. Herman, that any unusual hemorrhage or discharge in a woman who has had children is a reason for vaginal examination, for it may be the first symptom of cancer, and the nature of this disease can not be determined without local examination. In considering the local signs, the features which distinguish cancer in any part of the body must be taken into consideration.

When cancer begins as an outgrowth from the surface it may look like a growth of warts, or papillæ, or granulations on the vaginal portion, and the surface feels uneven or even rough. It may begin also as an ingrowth beneath the surface. It can be detected by an angry, livid red spot the surface of which is at first quite smooth. This angry color depends upon the vascularity caused by the new growth and upon its tendency to break down, which leads to minute hæmorrhages into the growth before the breaking down is extensive enough to make a breach of the surface. The livid surface of a cancer spot bleeds on being rubbed, so that a smooth, dark-red spot, bleeding on contact, is very suspicious. This is the earliest stage of cancer, and if there is a nodule that can be felt, the suspicion is still stronger. If the cancer has so advanced as to form a growth like a mushroom or a cauliflower, the diagnosis can scarcely be doubtful.

With regard to microscopical diagnosis, Dr. Herman thinks that the value of the microscope has been overestimated, and that to rely upon its use may lead to many mistakes. It may now and then, he says, reveal cancer in a doubtful case, but negative microscopical evidence should never be trusted. The

characters seen with the naked eye and the behavior of the growth should always be taken into account as well as its histology, and if the two conflict, the behavior is the more trustworthy. If the case is a doubtful one, behavior of the suspicious part under treatment is the best test. One or two applications of strong carbolic acid will improve the local condition, and the diseased part will cease to bleed on contact. If the disease is cancer, these applications will stimulate its growth, and the local changes will be more pronounced after such treatwent.

if there are symptoms indicating cancer of the cervical canal, and nothing is detected with the fingers and the speculum to account for them, the suspicion can be confirmed only by dilating the cervix. The liability to error in conclusions based on a microscopical examination of broken-off pieces, says the author, applies more strongly to this form of cancer than to that of the vaginal portion, as it is not possible to detect where the broken-off pieces come from. This form of cancer advances so rapidly, and the initial signs are so slight, that the opportunity seldom occurs for early diagnosis and treatment.

The Massachusetts Medical Society will hold its one hundred and thirteenth annual meeting in Boston on Tuesday and Wednesday, June 12th and 13th, under the presidency of Dr. James C. White, of Boston. The section meetings will be held in the Harvard Medical School, on Tuesday. The programme for the Section in Medicine, under the chairmanship of Dr. F. C. Shattuck, of Boston, includes the following: The Protective Power of Vaccination, by Dr. J. H. McCollom, of Boston; The Technique of Vaccination, by Dr. W. N. Swift, of New Bedford; and Radical Differences in Methods of Cultivation of Vaccine Lymph, by Dr. S. W. Abbott, of Wakefield. The special order for the Section in Surgery, under the chairmanship of Dr. F. K. Paddock, of Pittsfield, is a paper on The Cure of Carcinoma of the Breast by Operation, by Dr. W. T. Bull, of New York. The Shattuck Lecture will be given on Tuesday evening, by Dr. Thomas Dwight, of Nahant, on the subject of The Range and Significance of Variations in the Human Skeleton. The general meeting will be held on Wednesday, in the Mechanic Building, on Huntington Avenue. The programme is as follows: Ichthyol in Gynæcology, by Dr. Malcolm Storer, of Boston; Chronic Inflammation of the Seminal Vesicles, by Dr. G. W. Allen, of Boston; and The Frequency of Puerperal Sepsis in Massachusetts-its Diagnosis and Efficient Treatment, by Dr. Edward Reynolds, of Boston. At noon the annual discourse will be delivered by Dr. R. H. Fitz, of Boston. The annual dinner will be served at 1 o'clock P. M. in Grand Hall.

Acute Amygdalitis.-The Gazette médicale de Paris publishes an article on this subject in which the author treats of the ætiology, nature, pathogeny, etc., of the affection. Acute amygdalitis, he says, comprises simple infecting, suppurating infeeting, and grave infecting amygdalitis. It is rarely found in an isolated condition; when the tonsils are inflamed there is always angina more or less extensive. That amygdalitis is an infectious disease is proved by the general symptoms-which are sometimes serious-by contagion, by epidemics of angina, and by the presence of microbes, streptococcus and staphylococcus multiplying in the tonsillar follicles. The disease, then, is septic and infectious, local or general, according to the case, and may be suppurative, erysipelatous, phlegmonous, or furuncular. It is most common in children and in young persons in whom the circulation is active, and while the genital organs are developing. Other circumstances favoring it are enlarged tonsils, preceding attacks, calculus of the follicles, cold, uncleanliness of the mouth, traumatisms, and sores of the mouth which open the vessels and thus favor infection. The functional symptoms are a spon-

taneous smarting pain provoked by deglutition, radiating toward the ear, disturbances of the voice and the respiration, deafness, and difficulty in opening the jaws. The local symptoms are tonsillar hypertrophy, intense redness, ædema about the tonsil, a pultaceous coating, hypertrophy of the glands (follicular angina), and obliteration of the follicles. The inner surface of the cheek is painful, and the tonsils are hard and elastic to the touch; on submaxillary palpation there is painful tumefaction, for sometimes the carotid and submaxillary ganglia are slightly choked up. The general symptoms are variable according to the form and gravity of the infection. Among the non-suppurating forms of tonsillary angina are simple catarrhal and grave amygdalitis. In the latter the symptoms are generally severe, recovery is slow, there is collapse, and convalescence is long. Among the suppurating forms are parenchymatous amygdalitis, or tonsillar phlegmon (which is sometimes accompanied by sphacelus of the tonsils), and circumtonsillar phlegmon. The grave forms are the hyperseptic, in which death is rapid and hyperacute septicæmic accidents occur; the septic, which is serious; and the pyæmic, which is still more serious. In these forms abscesses make their appearance in the liver, the kidneys, the joints, etc. It is especially in these serious forms that complications exist, and they comprise three kinds. Some of them result from the transportation of the infectious agent to a distance, and are, primarily, nephritis, infectious arthritis, endopericarditis, pleurisy, peritonitis, which is rare, orchitis, and oophoritis, and secondarily, infectious paralysis (without the transfer of pus); secondly, purulent arthritis, purulent pleurisy, purulent otitis, etc. (from the transfer of pus). Others, resulting from local disorders provoked by pus, are suppurating phlebitis, ulceration of the internal carotid or of the internal jugular, which is very rare, and suppurating adeno-phlegmon of the neek. Still others result from the intensity of the collateral ædema, especially ædema of the glottis. With regard to the diagnosis, it is very easy to distinguish amygdalitis from some diseases, such as small pox, measles, scarlet fever, and typhoid fever. Clinically, the diagnosis lies usually between the nonspecific, diphtheritic, and herpetic amygdalitis. The prognosis is variable, according to the form of the infection, which is sometimes wholly benign, but often may become very serious.

Reflex Cough due to Ear Disease .- In a review of the current literature of otology, by Dr. H. Lavrand, published in the Journal des sciences médicales de Lille for April 21st, there is a summary of an article on reflex cough, especially auricular cough, by Dr. Guder, which appeared in the Revue de laryngologie. The author remarks that in many patients affected with ear disease the introduction of an instrument-such as a blunt hook, a curette, or a speculum-into the external auditory meatus provokes certain reflex phenomena, most commonly cough, which do not cease until the instrument is withdrawn. Although, he says, this reflex auricular cough has long been known, it has not yet been studied methodically. On exciting different localities in the external auditory meatus in two hundred persons taken as they came, the author has elicited cough in only forty-two. This cough occasionally takes on a character very distressing by reason of its persistence. He cites a case reported by Percy Jakins in which there were all the signs of beginning tuberculosis, such as cough, exhaustion, nightsweats, occasional delirium, and mucous râles throughout the chest. Both meatuses were plugged up with accumulations of When these were removed the pulmonary symptoms mended very rapidly. When the hearing is not perceptibly affected, the author continues, an examination of the ears is not thought of, and so the cause of a reflex cough often remains unrecognized. Still other reflex phenomena are caused by irri-

tation of the external auditory canal, such as sneezing, disorders of the sense of taste, and sometimes sexual excitement. In certain individuals digestive derangements supervene, and reflex disorders of the heart sometimes have an auricular origin. How, asks Dr. Guder, is the reflex cough produced? According to such authors as Hyrtl, Beaunis, and Bouchard, he says the auricular branch of the pneumogastric nerve discovered by Arnold has its origin in the jugular ganglion or else is given off from the trunk of the pneumogastric immediately below that situation. It proceeds by way of the jugular fossa and the Falloppian canal to the posterior part of the external auditory canal. As a matter of fact, auditory reflex cough is provoked only by irritation of the postero-inferior wall of the canal near the tympanum. Why, he asks, does not everybody suffer with this surjcular reflex cough? The only probable explanation lies in admitting that in certain individuals there is an anomaly of innervation at the bottom of the canal. The more or less nervous condition of the individual does not account for the differences observed. There are no distinctive characteristics of the reflex cough. Sometimes it is paroxysmal, resembling that of whooping cough; sometimes it is explosive, short, hoarse, and barking; unless there is at the same time a catarrh of the respiratory passages, it is not accompanied by expectoration.

The Examination of the Blood in the Diagnosis of Fevers,-The importance of a microscopical examination of the blood in simple anæmia is generally admitted. Its further value in the diagnosis of fevers is set forth by Dr. W. S. Thayer, whose study of anæmia following typhoid fever recently appeared in the fourth volume of the Johns Hopkins Hospital Reports. He states that the examination of a fresh specimen of blood will enable the physician to distinguish typhoid from malarial fever by the absence of the hæmatozoon called Laveran's organism. In tuberculosis, whenever there is any local inflammatory process, such as exists in the great majority of cases, a certain degree of leucocytosis or increase in the colorless blood cells is always present, showing that the number of overripe elements is distinctly increased. This is probably the rule also in cases of general acute miliary tuberculosis. This leucocytosis may be absent in some rare cases of miliary tuberculosis, where the primary focus of infection is not the seat of an extensive inflammation, though there generally is a high percentage of those leucocytes or white corpuscles whose nuclei are so contorted that they appear as "multinuclear elements." According to Ouskow, typhus fever shows no appreciable change in the blood from the normal. Of the other infectious processes with which typhoid fever may be confounded, the majority are usually associated with hidden inflammatory foci, causing a marked leucocytosis with an increased proportion of "multinuclear" non-staining cells. There is absence of leucocytosis in some cases of malignant pneumococcus infection, though a subnormal number of leucocytes has never been noted, or a diminution of non-staining cells with contorted nuclei. In any suspected case of typhoid fever the examination of the blood should never be neglected, for in the absence of leucocytosis and in the changed relative proportion of the different varieties of colorless corpuscles there are two valuable diagnostic symptoms, though neither may be pathognomonic. Where the case has existed for some time, and has perhaps shown anomalous symptoms, the change in the relative number of leucocytes is particularly striking. In such cases the discovery of a much decreased proportion of leucocytes having contorted nuclei, together with a corresponding increase in the large uninuclear and transitional forms, may decide the diagnosis.

Milkmaids and the Spread of Typhoid Fever.—There ander's Operation for Sho are three recognized ways by which the germs of typhoid Uterus (Sixty-four Cases).

fever may enter milk. Typhoid effluvia may be absorbed by the milk; the milk may be adulterated with impure water containing the microbes; the milk vessels may be washed with water befouled with them. In the Lancet for April 21st Dr. J. J. Wesley reports a fourth source of contagion to be the milking of the cows by a person whose hands have been soiled with typhoid-fever dejects. An epidemic of typhoid fever prevailed in a country district where a number of dairy farmers daily sent milk to a creamery at which the milk from all the farms was mixed, the cream taken out by a centrifuge, and some of the skim-milk, which in this method, is known as separated milk, sent back to the farms and some sold in the villages. Out of eighteen cases of typhoid fever in the country, seventeen were traced to the use of this separated milk. Of twenty-three patients in the villages, nineteen had used separated milk. There were sixty-one cases in all which were clearly traceable to the creameries. A careful investigation showed that the contagium reached the milk from the hands of the dairymaids. The nurse of the first typhoid patient was a milker on one of the farms, and undoubtedly spread the fever through the mixed separated milk. The dairymaids on several of the farms had acted in the dual capacity of milkers and nurses. It was found that many of the cows could not be thoroughly milked unless both hand and teat were kept moist, and it was almost impossible to draw from some of the cows even a small quantity of milk with a dry hand. The moistening with milk washed the typhoid dejecta from the hands to the milk-pail, where they multiplied with frightful rapidity. The district was put under the strictest regimen of cleanliness with gratifying results.

International Medical Congresses,-The Union médical quotes from the Presse médicale belge the following passage apropos of the recent Rome congresses: "Congresses are no longer great scientific sessions in which serious discussion goes on and in which one, therefore, is made to struggle with some great question of pathogeny and therapeutics. With the exception of two or three reports in which original conceptions are conspicuous for their absence, with the exception of the proposition or general review of a scientific question, followed not by a debate, but by unanimous plaudits, congresses are no longer anything more than a rendezvous for friends, an occasion for making a show, an excuse for leaving one's country and one's patients for a few days 'scientifically,' or a show of orators or readers of medical observations, which are merely indicated in the columns of a journal. We are persuaded that, to give to congresses their real scientific, and not merely their numerical and decorative, importance, it is time to change their scope and their organization. Certain great questions or problems should be put down for discussion. Let a reporter-general be nominated to condense the subject and indicate its leading outlines -nothing more, but especially let the report be followed by counter-reports and discussions, and the results obtained will be astonishing."

A Case of Multiple Tæniæ.—At a recent meeting of the Societé des sciences médicales de Lille, reported in the Journal des sciences médicales de Lille for April 7th, M. Guermonprez presented, on behalf of M. Lenys, the heads of thirteen tapeworms which had been passed simultaneously by a single individual. The species is not mentioned.

The New York Academy of Medicine,—The special order for the meeting of Thursday evening, June 7th, was a paper by Dr. Paul F. Mundé, entitled Ten Years' Experience with Alexander's Operation for Shortening the Round Ligaments of the Uterus (Sixty-four Cases).

# THE NEW YORK MEDICAL JOURNAL, June 16, 1894.

Rectures and Addresses.

# THE NERVOUS SYSTEM IN DISEASE,

AND THE PRACTICE OF MEDICINE FROM A NEUROLOGICAL STANDPOINT.

By C. H. HUGHES, M. D., st. louis.

(Concluded from page 710.)

Neurodermatological Advance.—Mr. Malcolm Morris, in his presidential address before the Harveian Society of London, reviewing the progress recently made in dermatology, after noting the fact that we now recognize the precise microbic agents which produce lupus, scrofuloderma, impetigo, leprosy, and glanders, and speaking of the "new light" which experimental pathology has thrown on the nature of disease processes and the factors concerned in their production in the skin as in other organs, says:\*

"Almost the only distinct evidence of progress apart from local treatment to which I can point, is the fuller recognition which has been arrived at of the influence of the nervous system in the production of skin affections.... The knowledge of the intimate pathological connection between the nervous system and the skin gives the key to the successful treatment of many cases which defy all local measures."

The same light has lately dawned on gynæcology and every department of medical practice. We are approaching an era when the whole patient is to be treated, no more only a part or organ solely, and neurology will have a paramount place in general clinical medicine, notwithstanding the recognized and merited advances of bacteriology in pathogenesis.

Certain Heart Affections Proceed from the Brain.—What is true of the influence of the nervous system over the stomach in dyspepsia and the lungs in the pneumonia of influenza, is also true of its influence in the production of certain diseases of the heart. They come from different conditions of the brain, and here again has medicine, in its work for the world's welfare through physiological research, faced the prejudices of a frowning world against the so-called cruelties of vivisection.

1. .

Though the heart of a frog removed from the body will pulsate for hours, if fed with blood or blood serum, and will continue to beat even when divided into sections except at its apex, and even this will beat if tied to the end of a tube and fed under pressure, its conditions of nutrition in vertebrates are determined directly by the nervous supply of the organs and indirectly by the blood (Mills), and the influence of the cardiac nerves becomes more pronounced as we ascend the animal scale, and in the heart of a frog there are ganglion cells in the sinus venosus, in the auricles, and in the ventricles (ganglia of Ludwig, Remak, and Bidder). They are also in the warm-blooded animals, such as dogs, sheep, etc.†

When the heart is severed from the central nervous system by section of the vagi nerves, or destruction of the vagus center takes place by traumatism or disease, profound changes in the heart's structure ensue. This points to central trophic influence through the vagi and to the often central nervous origin of heart disease. The regularity of the heart's rhythm from and strengthening of its beat through vagus stimulation and central stimulation, as by certain volatile and internal stimulants, is suggestive.

We are now able to understand how many disorders of the heart are coincident in their inception with occasions of fright and worry and anguish, sudden accesses of extreme ire, disappointment, prolonged enforced vigilance, and other brain strains. These, as Mills tersely says, point to influences of a central origin as greatly affecting the life processes of this organ.

Czermack, by pressing a bony tumor in his neck against the vagus nerve, and Hermann and Colonel Townsend, by repeatedly suspending the heart's beats at will (the latter once too often, for he died from his final experiment), also proved the central and vagus nerve influence over the heart. Nervous influences certainly play no small part in the causation and modification of the heart, and, with Mills, we would "extend such a view to all parts of the body," especially in man. The source of the heart's diseases is often in the brain and other parts of the nervous system, and so is the source of many other diseases for which only the organ displaying the functional disorder, and the blood which nourishes it, are treated, whereas we should oftener treat the whole man, nervous system and all, but the nervous system especially, if we would be most successful.

Now, therefore, in a newer, broader, truer sense than ever before, do we recognize the monism of man. Not in the sense of the philosophical schools, but in a psychoneuro-physical sense in our survey of his physiopathology. In estimating the causes, concomitants, and sequences of his diseases, we consider the whole man in his psychoneuro-physical relations. As the "medulla oblongata is functionally the ruler of vegetative life," so it governs and influences many diseases, as the psychical and psychic centers of the cortex influence it and the centers below it, as the rectogenito-urinary centers of the cord, etc.

As we recognize psychic influence over our physiological life, over physical and mental habits, so must we come to acknowledge it more generally in our dealings with disease. The physiological law, that habit in the psychical life de-

tractility is modified by medulla and vagus stimulation, to the degree of arrest, slowing, enfeeblement, or intermittency.

When the vagus influence is altogether inhibited, the heart's action is increased in force and frequency, while section of both vagi leads to histological alteration and fatty degeneration. The sea turtle's heart has been suspended through vagus stimulation for six hours, causing its death. The heart dilates with or without blood during vagus arrests from vagus section, drug impression, or electric excitation. The heart may be reflexly inhibited by gastric and abdominal reflex irritation, flatulent dyspepsia, the Klopfersucht of Goltz, etc. If one or both vagi are intact, stimulation of the medulla arrests the heart. The conclusion of a cardio-inhibitory and accelerator center in the medulla, which influences the heart through the vagus, is the obvious teaching of physiology.

<sup>\*</sup> British Medical Journal, January 27, 1894.

<sup>†</sup> So that, while conceding spontaneous muscle-cell pressure and protoplasmic contractility, we know that in certain cases cardiac con-

velops a tendency to recurrence, is also exemplified in the disposition of certain diseases to recur, and the interrelation between muscular and mental tonus suggests the importance of maintaining the psychical tonus in the treatment of all diseases, and the successful therapeusis of hypnotism proves it in many.

As it is difficult to believe in force existing not in contact with matter, and without matter existing on which force can display itself, so it is difficult to conceive of the existence of disease in the human body without an influencing or influenced—i. e., disturbed—nervous force.

Henry Maudsley has likened the physiological life of the cerebro-spinal centers to the mutual interrelated and subordinated movements of the companies, battalions, and brigade of an army under command of the higher ganglion cells of the headquarters in the brain, and mental disease to mutiny and rebellion. Huxley has likened the body to "a machine of the nature of an army, not that of a watch or of an hydraulic apparatus. Of this army each cell is a soldier, an organ, a brigade, the central nervous system the headquarters and the field telegraph, and the alimentary and circulatory system the commissariat. Losses are made good by recruits born in the camp, and the life of the individual is a campaign conducted successfully for a number of years, but with certain defeat in the end." Each tissue, under the trophic influence of neural communication with its appropriate nervous headquarters, conducts its own repairs-i. e., replenishes its own forces. When proper physiological conditions, including neural connections, are maintained, each tissue in the animal economy correlates its own proper life force. Destroy a trophic center, and the part it innervates atrophies; sever a motor nerve, and the muscle it supplies is paralyzed; cut a sentient nerve, and no power of our art will restore sensibility over that channel that does not reunite or reproduce the nerve. Our aim in the practice of medicine, then, should be to save the nervous system and to conserve neural integrity and force in relation to all parts of the organism suffering under the depressing influences and destroying tendencies of disease.

This should be our aim always, whether we are enabled to make a satisfactory local diagnosis or not, for if we succeed in saving the nervous system absolutely, we save the man; for it is only after disease makes its final resistless inroads here that our patient dies.

Hæmophilia and the Vaso-motor System.—The neuropathic source of hæmophilia in the vaso-motor system is more probable than any asserted dyscrasia of the blood, and cholera is so largely a condition of nervous prostration in its symptomatic expression, that if we treat it on this theory, keeping the patient absolutely recumbent and give him copious hot-water drinks and enemata, we are more apt to save him by this than by any other one plan. Of course, the comma bacilli should be searched out at the same time with our hot drinks and colon clysters, and destroyed so far as may be practicable; but it is the damage done to the nerve centers that we wish to guard against in this disease until the collapse stage passes, the bacilli are destroyed, and reaction comes on. Cold colon douches are likewise of some benefit. I think the water does the works

and not the soap, in Elmer Lee's plan of treatment, which I uphold on the physiological principle that the abdominal ganglionic centers and, by eccentric impression, the spinal nervous system are favorably impressed by his method, while such bacilli as the water can reach are washed out of the intestinal tract; but these are not the most of them.

To divest ourselves of undue skepticism in regard to the influence of the nervous system in the development of what we are accustomed to call disease, but which is often the sensible pathological product of a morbid process, we should recur often to the physiological possibilities of the mechanisms of neural control over the arteriole system and of sensation and motion.\*

Body Temperature and Fever Dependent on the Conditions of the Nervous System.—That remarkable phenomenon, the uniformity of the temperature of the human body at all latitudes and in all seasons, is due to the regulating adjustment of the circulation, perspiration, etc.; to environment, through the nervous system; and when the temperature is disturbed it is due to irritation, mechanical, chemical, or toxic, of the nervous system, as in traumatic violence, microbic, septic, or drug disturbances.

It must by this time be apparent from what we have already said that the intimate physiological relations between the nervous and the vascular and glandular systems justify these pathological inferences and confirm the clinical facts,

"The nervous system has so close an alliance with the functional activity of the secretory and excretory glands of the body that emotional disturbances, according to their character, act as depressants or excitants of the functional life of these organs. Some of the more common of these effects are every-day familiar facts, as when the flow of tears is excited by grief, or the secretion of saliva and gastric juice by the smell of food." And it is believed that "in the same manner as the superficial glands are easily influenced, so, in all probability, are the blood-making or ductless glands † regulated and controlled by the organic nervous system."

\* Brown Séquard, for instance, produced hæmorrhage into the auricles of guinea-pigs by section and irritation of the restiform bodies in the medulla, and flushed the neck and face by section of the cervical sympathetic. In this we have the explanation of hæmatoma auris and cerebral hyperæmic states.

It is through the nervous system that we may understand how the hair turns in melancholia and may thicken in chronic mania or dementia of the less distressed and more stupid and inactive forms; how its color may turn from dark to white and back again to dark, with the access and recoveries of recurrent insanity; how it may become glossy and dry, erect or flat, be lost and regained under certain mental conditions; and how the teeth may decay, the bones and nails grow brittle and the skin become harsh from the same cause; and how, from neu ritis, the nails are transformed, and the limbs waste as well as fail is sensibility and mobility, besides the eczematous, pigmentary, and horn changes of the skin from nerve injuries.

† Dr. A. D. Rockwell, in the New York Medical Journal, Decembe 10, 1892, maintaining the nervous origin of jaundice, said he had ha occasion to see and treat a considerable number of cases of jaundic dependent upon a great variety of causes, and he had been impresse with the frequent occurrence of cases due to deranged innervation, ir terfering with the normal metamorphosis of bile. Acute atrophy, i which the secreting cells were rapidly disintegrated and the function of the organ arrested, appeared to him in many instances to have

The Nervous System and the Liver.—The influence of the nervous system over the liver was believed in by the ancients, who, mistaking coincidence for sequence, attributed melancholia to atrabilis. Murchison asserts a well-observed fact that the secretion of bile is interfered with by prolonged mental anxiety, worry, and incessant mental exertion, and that sanguification and blood changes, in which the liver takes part, often result from mental causes.

I think we need no longer doubt this, or indeed any possibility to neural influence, when we see pernicious anæmia follow degenerations of the spinal cord, and progressive muscular atrophy and anæmia follow cerebro-spinal concussions.

If the mind has such potency, how careful should physicians be of their demeanor or speech before patients! How guarded as to prognosis! And the surgeon, how careful should he be as to the undue and inopportune display of his operative armamentaria! With these facts in view, the propriety of large medical and surgical wards, where the sufferings and death of one patient may be readily known to the others in the ward, is questionable. Other obvious considerations needless to mention here are suggested in this connection.

These neural connections, direct and indirect, between the centers of the brain and the circulation, the viscera and the secretions, reveal the physiological basis of all forms of psychotherapy, of faith cures, mind cures, and modern miracles, of the principles of which those who perform them are usually ignorant; also of hypnotism and its therapeutic results.\*

Leucæmia us a Neuratrophic Blood Disease.—Leucæmia is another and most remarkable condition which may result from profound nervous exhaustion or shock, or from malarial neuratrophia, and shows how the blood may change through nerve influence, as cretinism and pachydermic cachexias show the relationship of thyreoid and nervous degeneration, and as thyreoid extirpation also proves.

The Rattlesnake Poison First Produces a Deadly Nervous Shock.—If the remarkable blood-cell changes of this disease may originate in morbid neural impression, it would seem unnecessary to go further for proofs. But the poison of the rattlesnake and other toxic substances may kill through immediately fatal shock without detectable lesion, though grave structural changes follow, especially in the destruction of the blood's fibrin, and later putrefaction,

purely nervous origin; and very often the first symptoms of the disease occurred immediately after a severe fright or an outburst of passion in a person previously healthy. An impression made upon the brain appeared to be reflected to the liver and to derange its nutrition. Even cancer of the liver appeared sometimes to result from the functional derangement induced in the first instance by mental trouble. So this condition appeared to him.

\* The wise physician combines chemistry and a scientific materia medica with honest and hopeful mental impression, establishing in the patient where he can, and when it is justifiable by the clinical facts without deception, a buoyant psychotherapeusis in the patient himself. The lengthened visage, the hopeless foreboding, the dismal and solemn aspect, and funereal demeanor on the part of the physician are not only out of place and unjust to the patient, but are bad therapeutics.

in the case of crotalus poisoning, if the patient survive any considerable length of time.\*

The nervous system is the supreme ruler in the organism. When disease enters, it is weakened; when death takes place, it is dethroned. The germs of malaria, tubercle, cholera, typhoid, tetanus, etc., or the living virus of any fever, make no fatal inroads until they break down and destroy centers of neural control and resistance.

Whatever view we may take of bacilli, bacteria, or cocci which our glass may reveal to us in the damaged organism, whether we regard them as carrion about a carcass. rats forsaking a sinking ship, thieving, destroying, or scavenger parasites, one thing is certain-viz., disease becomes manifest only after the mechanisms of neural sensation, emotion, ideation, or control reveal it, for, as I have elsewhere said, the nervous system is the central executive and universal sentinel system of the organism. It governs and legislates for the physiological body, exercising moving, restraining, regulating, or inhibitory power over organic processes in health and in disease. It has its subordinate tributary and sustaining forces in the glandular, vascular, osseous, and other systems. It commands, governs, and regulates them, and they influence it, as the citizens and subordinate officials of the State may influence and even govern the chief executive or the king.

Raynaud's disease, with its local asphyxia and symmetrical gangrene of the extremities, though its cause may be uric acid, as Haig (*Uric Acid in the Causation of Disease*, second edition, p. 201) maintains, is manifest to us, as Raynaud believed, through spasmodic contraction of the capillaries, as the gangrene of ergotism is.

Haig contends that the uric-acidemia of gout and rheumatism "contracts the arterioles and produces high arterial tension," and that glycosuria is the alternative of and contemporaneous with gout, Ord maintaining that the congestion of the liver is due to high arterial tension, while Pavy, according to Haig, credits diabetes to a vaso-motor paralysis of the chylopoietic circulation, which allows arterial blood to be supplied to the liver in place of venous (British Medical Journal, 1883, pp. 863 to 866).

Haig concedes that the hepatic congestion dependent on the state of the vaso-motors develops the saccharine diabetes, thinks the uric acid causes that, but attempts no explanation, except a dietary one, of the uric acid in the blood.

If I had the time to write a book on this occasion, I think I could show the nervous system to be primarily at

<sup>\*</sup> How speedily the symptoms of this poison follow, if death be not instantaneous; the cry of terror, the giddiness, the syncope, the vomiting, the prostration, the rapid, irregular, imperceptible pulse, the sunken eye, the swollen face and body, the jaundiced, cold, clammy, vesicled skin, the delirium, sleeplessness, torpor, coma, involuntary intestinal and vesical discharges, tremors, convulsion, and death! First the nervous shock, and then the blood disorganization and organic dissolution.

Drysdale examined the cases immediately fatal with the best of lenses and found no lesion. The nervous system was directly stricken, and life, of which the cerebro-spinal and ganglionic systems in man are the representatives, ceased. The physiological barrier wall in the nervous system is broken and disease invades.

fault in the uric-acid diathesis, and that migraine, epilepsy, morbus Brightii, diabetes, and melancholia, which attend upon the chronically gouty and rheumatic, and alternate with these states, are varying neuropathic states with uric-acidæmia, albuminuria, and sacchæmia as their sequences. But this would be profitless. The practical clinical and therapeutic lesson is to correct both the abnormal blood and the faulty nervous states.

The contracted arterioles which raise the tension in the arterial system and diminish the circulation through the organs and tissues of the body need remedying, as well as the uric-acidemia, the "hetero-albuminæmia, albuminuria, etc.," and the deficient circulation and the deficient metabolism of organs and the disordered assimilation, as well as diet; for some persons may eat any kind of food and have neither gout nor rheumatism, no diabetes nor Bright's disease, so long as the governing nervous system maintains the physiological equilibrium and sustains and secures it against pathogenic forces from without and within.

A change in the weather or a certain exposure sends one man to bed with rheumatism, another with pneumonia, and a third comes down with remittent or intermittent fever, or phthisis. We say uric acid in the first case, pneumonococci in the second, malaria in the third, and tubercle bacilli in the fourth.

But why do these morbific forces now more than any other time come so opportunely and seize upon their prey?

We say it is because the vitality is lowered and the organic resistance is lessened. What is that vitality, that organic resistance, which permits one man to brave an atmospheric or climatic environment with impunity from disease, in which another falls a certain victim? What is it that permits one man to eat everything without being made dyspeptic, while another can swallow scarcely anything without suffering the gastric distress of indigestion ? We say one has a weak stomach; but if we take into account the whole man we find it is the brain of the dyspeptic rather than his organs of digestion that has been always punished by its owner's imprudent and reckless habits, though the stomach, too, may have been abused. We get a similar answer in regard to the remote causation or determining factors of disease of many other organs. We have invented, for evasive answer, certain elucidating terms, as idiosyncrasy, diathesis, morbid proclivity, inherent organic tendencies, etc., and we make many special explanations, like the little fibs the schoolboy tells to extenuate a folly, each leading to some other and bigger fib, until he finally realizes that honesty is the best policy and he finally owns

My answer has already been intimated. I can not on this occasion weary you with further detail in elucidation.

I say only in conclusion, to forestall certain criticism, that, though the primal potency of the nervous system resides in the sarcode, much of its potentiality, in the highest and most complex animal life, seems to have passed in process of evolution from protoplasm to nerve centers, and the most there is of man is his nervous system. In this system reside, in a highly evoluted form, spontaneous and reflex motion, sensation, and the governing influences of

assimilation and reproduction. What should we not expect of such an organism impressing and impressed by disease!

This brief survey of a broad subject brings us across the century twenty years before the one now soon to close had begun, to the immortal dictum of Cullen, the truth of which the progress of medico scientific research in cilinical medicine now confirms: "Quantam ego quidem video motus morbosi fere omnes a motibus in systemate nervorum ita pendent, ut morbi fere omnes quodammodo Nervosi dici queant."

And now in the sunlight of advancing science and of the approaching twentieth century, I proclaim that neuriatry and the practice of general medicine are practically one.

The practice of medicine is rapidly becoming one of neurological methods, of neuriatry and psychiatry, and the best neurologist, all other attainments being equal, must of necessity make the best general practitioner. What Lord Chesterfield said of a Christian gentleman, I would paraphrase and say of the neurologist, that he is the highest type of physician; and of medicine as a whole, with Hippocrates, it is of all arts the most noble.

Thus much, and yet not a moiety in regard to the relation of the nervous system to disease and practice! Thus much of neurological progress relative to general medicine. Obviously we can not now enter into the marvelous advances and wondrous resources of modern medicine. In the pages of a thousand volumes and the works of a thousand modern hospitals, her glorious record is partly made for the welfare of man as the nineteenth century recedes into history. But there she stands in her grace and grandeur, the peer of all professions! Ever faithfully by the side of man, from the cradle to the grave, in the hour of his saddest need, mindless of home or creed, she bends with pitying, substantial aid over his suffering and prostrate form, and lends strength to his weakness.

Handmaiden of sweet charity and exemplar of the golden rule, she unshackled the lunatic and brought him from his dark and dreary dungeon into light and liberty while theology was yet calling him demon or devil-possessed, and she now extends her helping hand to the inebriate while the world yet condemns him and largely withholds its sympathy. She has likewise extended her protecting charity to the epileptic, the hysteric, the victim of chorea or St. Vitus's dance, and the so-called creatures of obsession.

She has influenced courts to modify the former harshness of their ruling toward certain classes, and caused them to recognize disease and degeneracy of brain in extenuation of crime, thus tempering justice with mercy toward the organically weak and maimed in brain and mind. Judicial theories of what should constitute insanity and allied conditions [exempting from responsibility to law, have given way to clinical fact ascertained through psychological expert testimony, and the "knowledge of right and wrong" test of mental aberration has, in consequence, ceased to be the sole criterion of responsibility in questions of insanity before the law.

The Treatment of Inebriety.-America was the first country to adopt, and the great Rush was the first physician to recommend, the "establishment of a hospital in every city and town in the United States for the exclusive reception of hard drinkers," and to regard the drink habit as a disease, and advise the blending of medication with religious and moral suasion. And how many regular hospitals, assisted by our State laws, are saving the inebriate from that destruction from which neither his own will, nor moral suasion, nor any other influence could rescue him! Yet no monument at the nation's capital bears testimony of the people's gratitude to this great physician and signer of the Declaration and surgeon of the Revolutionary Army. I can not help this digression when I reflect upon this nation's long-neglected debt of gratitude. I repeat the plea I made last year. Benjamin Rush's name is immortal, whether his memory is preserved in monumental bronze or not; but the Government owes his memory, his country, and the world this debt, and every consideration of delicacy, of decency, of justice to its meritorious dead, and of patriotism demands its honorable discharge. I have elsewhere discussed this subject in extenso.

This is the fruit of our friendship for the unfortunate lunatic, and in American courts the product of ripened seed planted in the field of forensic psychiatry by that eminent and immortal American medico-jurist, Dr. Isaac Ray, of Philadelphia, whose great work, the Jurisprudence of Insanity, was the beginning of a memorable era in medicolegal progress, and gave American psychiatry a distinguished standing before the courts of the country and of the world. In this classical American work the disease of brain and change of character criterion received their clearest elucidation after Andrew Combe, and since the decease of this great American alienist, that other and congenital form of mental disease, paranoia, has received clear elucidation and distinctive differentiation through the contributions of Kiernan, Spitzka, McLane Hamilton, Mann, and other American writers following the treatises of Erb and others abroad.

The hospitals for the insane, which made the names of Pinel, the Tukes and the Chiarugis, and later alienists immortal, among them our own Kirkbride and Tyler, have been followed by homes and schools and hospitals for the feeble-minded, in connection with which Edouard Seguin, of America, has an undying place in the philanthropic heart of the world, along with that of Froebel and Howe, in Germany, from whom Seguin got the inspirational inceptive idea, and patience of training and improving the mental evolution of these unfortunate defectives, and American surgery, thanks to Dr. William Fuller, of Grand Rapids, Mich., first suggested (in the face of the Old World's sneers) a possible operative remedy for the relief of certain of these defectives, the feasibility and value of which have lately been acknowledged abroad and demonstrated at home. Linear craniectomy has proved its right to a trial. It will not relieve microcephalic or porencephalic idiocy, but in other forms of arrested brain development through premature contraction of the cranial vault, this procedure has made it possible for the brain to develop, the speechless to speak, and the convulsive to cease their spasm, just

as other forms of craniotomy have done for pressure aphasia and epilepsia.\* This devoutly-to-be-wished-for consummation will be hastened through the general use for cerebropathic investigation and description of the marvelous piece of neurological mechanism which I now show you as the ingenious handiwork of an American anatomist, not yet so widely known to fame as he deserves to be, Dr. J. P. Fuller, of Grand Rapids, Mich. In this unique contrivance the brain has been represented in thirty-seven transverse sections, hinged together in natural form and shape, with the superimposed superficial psychomotor centers; the downward paths of conduction to the cord and the entire brain in its median and spherical and interior aspects are separately and relatively shown.

The saving triumphs of brain surgery in other directions of prudent neurology are now simply marvelous, but more marvelous far than this wondrous work of salvage will be the saving of the brain and nervous system from the necessity of surgery, the mark at which general medicine and neurological medicine are now aiming, and a goal much nearer reached now than in the past.

Should men contest the claim of medicine to being the greatest of the world's benefactions, we reply, the germ theory of disease causation alone, with its applied antagonisms, hygiene, antisepsis, perfect cleanliness, and resistive and tolerant inoculations, has done, is doing, and is destined yet to do more for the physical welfare and salvation of mankind than all other causes of man's comfort conceived in the mind and heart of man.

\* Dr. J. F. Binney, of my own Ntate, has this year reported in the Annals of Surgery, for April, one such successful operation, and Paschill reported in the International Medical Magazine another last year, both being followed by marked mental improvements. Each of these gentlemen likewise reports other cases without satisfactory results. Frank, of Chicago, has paved the way, I think, to the ultimate success of cerebral ventricular puncture.

† Dr. Fuller says in his preface to the great demonstrative work of his: "When a medical student, the author of this work experienced great difficulty in understanding the anatomy of the brain from plates and descriptions in books, and recognizing the fact that compared with the number of students, the opportunity of studying the anatomy from the natural brain is rare, he bas carefully prepared a series of casts from actual dissections and casts, which he hopes will materially aid the teacher, and render the task of the student much easier.

"The dissections presented in this specimen are made from photographs taken of sections of a carefully prepared brain, cut a sixteenth of an inch apart and perpendicular to a line drawn from the external process to the occiput.

"Familiarity with these plates and their situation in the brain will enable the necroscopist to recognize, at a glance, any section that he has made of the natural brain, and to select the proper plate from a book of similar plates which accompanies the preparation, upon which to describe any lesion found, and which he can attach to his report of a post-mortem examination, so that others also familiar with the position of the plates comprising this series will be able to locate the lesion described.

"In this way a more ready understanding will be effected between neurologists, and it is hoped that, by this means, together with the careful observations of symptoms, the functions of many parts of the nervous system, now obscure, may be more clearly understood.

"This preparation is also invaluable to those interested in the surgery of the brain, showing, as it does, the relation of the external marking with deeper structure beneath." But for our applied teachings of hygiene, the world having its population in the last one hundred years nearly trebled, and civilized life having become so complex and degenerating in populous centers, the race would now be on the road to extinction.

The world is beginning to clean up, and mankind to recognize the necessity of cleanliness.

We are promoting this antisepsis on our part in giving to man the purified air of heaven and the waters of the earth freed from pollution. The air and water, and the spirit in man to conceive and apply measures for their purification, together with the uncontaminated and uncontaminable sunlight, are the direct gifts of God. taught mankind the value of cleanliness, the life-saving and prolonging value of physical and moral purity, and, putting our precepts in practice, when permitted, we put back pestilence and turn death and decadence from individuals and peoples. We are not gods of the air, but we walk the earth as watchful, pitying gods in the service of man, saving him from pestilences that walk in darkness, and of which he knows nothing, save in their destructiveness, until medicine enlightens him and destroys the destroyer of his health and strength and attendant happiness. But for the interposing monitions of medicine, man would not to-day be awakened to the danger of making a beverage of the attenuated liquid pollutions of the soil and, falling ill all unconsciously with typhoid and other maladies, as in the days of the not far distant past, reverently submitting to the mysterious ways of the all-wise Providence, as his remoter ancestors attributed all affliction to the wrath of offended deities. So little a thing as the timely boiling and filtration of all drinking water will confer a boom on mankind, in warding off disease, which can not be computed. The application of the discovery of Jenner is as nothing in comparison-not even the great disease-averting and life-saving discoveries of Pasteur could be so potent.

As "the sun smiles on the earth, and the exuberant earth returns that smile in flowers," so do the silent ministrations of our noble profession fall upon a recipient world, which blossoms in healthful response. Our ministrations of medical charity, like those of mercy, drop

"Like the gentle rain
Upon the place beneath:
Blessing him that gives
And him that takes."

Noble followers of a glorious vocation, grand and beautiful profession! Sublimest and best of the callings of men, save that alone of the Great Physician of Galilee, whose example encourages us and whose voice approves.

Besides the ten thousand hygienic resources for warding off disease and promoting the world's comfort which it unconsciously and, without thanks to our beneficent profession, daily employs, Medicine now mitigates and annuls pain through analgesics and anæsthetics (local and general), and contributes to human comfort under the most painful circumstances to a degree far beyond that of any other physical benefaction to mankind. Medicine has minimized and trained the lightning so that it ministers to

the relief of human misery and the cure of disease. She has made of it a search-light for the human body, an assuager of pain, a producer of sleep, and a destroyer of destruction.

The boon of hypnosis and narcosis under the many methods for its induction known to our art, saving the insomniac from the precipice of mental overthrow or neural failure in the lower centers of the cerebro-spinal axis or peripheral nervous system; the power of antisepsis, and through it the wonderful procedures and possibilities of modern surgery, and this fin-de-siècle hygiene; the many and marvelous therapeutic and hygienic advances in promoting the phagocytosis of the toxic bacteria, the destruction of the ptomaines, and in other directions of relief and cure; the discoveries of pathology, histology, medical chemistry, biology, neurology, psychology, psychiatry, and the contributions of surgery, gynæcology, ophthalmology, otology, laryngology, proctology, and the other specialties of study and work, have made the later decades of the present century the most memorable in resourceful discovery in the history of medicine or in the history of mankind.

Intravenous injections of immune animal blood serum promise much for the cure of phthisis and other chronic contagious diseases, and there appears good therapeutic promise for the coming years in mycodermic medication.

These grand achievements give us hope and promise of even grander contributions to the weal of mankind before the close of this final decennium of nineteen hundred.

Medicine has made the Pontine marshes of ancient Rome, the jungles of darkest Africa, comparatively safe to the traveler, and the valleys of the Nile and the Mississippi are no longer menaces to health. Quinine, eucalyptus, picrate of ammonium, and tasteless Fowler's solution have augmented human happiness and spread the commerce of civilized nations beyond computation. The world applauds its Livingstones and Stanleys, yet omits its meed of praise to those who have made their discoveries and the fruition of them a possibility.

Thus you see medicine ever advances toward its final goal-the health and consequent happiness of mankind. Thus we see, though with contracted view only, from this cursory survey, how much the past few years have done in the direction of medical advance. Thus we see that this great profession, the uplifter, friend, and benefactor of mankind, though the jest betimes of the world's great wits, continues its too-little-appreciated benefactions. Its votaries, forsaking or ignoring common routes to glory for paths of duty, have gone on ameliorating human misery and conserving and saving limb and health and life, and, through health, the welfare of the State; deserving, but not receiving, the conqueror's word of praise; marking the march of medicine with blessings on mankind, and deserving the world's gratitude far beyond what the world has ever recognized. In the fierce contentions of mind with mind and strain of modern business and professional life, and in man's contests with Nature and battle with the elements, medicine preserves and fortifies man's organism for the fierce fray, that he may fight on and conquer success, prosperity, and happiness for himself, for his family, and for the commonwealth.

. . .

When will a gratefully appreciative nation erect suit able monuments to our workers, our warriors, and our martyrs in the glorious cause of human happiness and human progress? For without health, man is nothing. In the struggle for the survival of the fittest he falls in the fight for existence, and becomes the victim rather than the vanquisher of his environment, and nations do likewise.

quisher of his environment, and nations do likewise. The world owes medicine much. When will it ever re pay even half the debt? It will be when "isms" and "pathies" in practice are dead; when the now vanishing days of sectarian theories shall have passed away forever; when a unified profession practicing in the faith and teach ings of true science shall have its legitimate combined in fluence over all of the people. It will be when students are taught a sufficient length of time (five years or more) in our medical colleges to enable them to master the prin ciples of medical science and the precepts of medical practice, and to practically appreciate the ethics of their profession. It will pay back the debt in tributes of honor and glory, and adulation, and in monuments of marble and bronze, when human progress shall have reached that high stage of evolution when there will be more renown for him who saves life in the name of charity than for him who takes it in the name of national glory; more glory for him who builds up than for him who tears down the fabric of human happiness. In that on-coming day of human enlightenment the true physician will be esteemed above the warrior. Nations will give him merited places of honor in ministry, in cabinet, and in council, and on tented and battalioned fields. Then it must needs come that the physician will assert and secure his peerage among the people. History will then give medicine an illumined and illustrious niche in her temples of enduring fame, and the glorious deeds of her worthy sons will be justly immortalized in the poet's song. America will then render long-neglected memorial justice to her great medical benefactors. Bronze and marble forms of her great dead doctors, who have dared and done more than warrior or statesman for the public weal, will adorn her public parks and grace her publie halls. The enlightened citizen standing beneath the dome of the nation's capitol, as he looks upon the immortal names there inscribed, will see those of America's great physicians written alongside of her other philanthropists, her jurists, and her presidents. American philanthropists will read their names there inscribed "in letters of gold and in pictures of silver," and revere their memories as the patriot now reveres the memories of Washington, of Jefferson, of Franklin, and of Patrick Henry. The names and remembrance of Benjamin Rush, of Ephraim McDowell, of Marion Sims, of Beaumont, of Crawford, of Jackson, of Bowditch, of Agnew, of Gross, of Wells, of Long, of Eve, of Gaston, of Marcy, of Mitchell, and of Mott and their good work for the weal of the world will be as immortal as those of our Clays, our Websters, and our Bentons. Every patriot will revere them, because they have contributed to conserve the health of the public, realizing that in the good health of a people is their happiness, their physical, political, mental, and moral power, and to be without this power is to be as pygmies among the nations, puny in prowess, I

and pitiable in all that makes man or nation great and

#### PALUDISM IN CHILDREN IN NEW YORK.\*

By HENRY DWIGHT CHAPIN, M. A., M. D.,

PROFESSOR OF DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The rarity of true paludism in New York and the fact that children do not appear very susceptible to malaria! poisoning renders this subject a somewhat difficult one for accurate study in this locality. The present notes are based upon an analysis of fourteen cases in which the diagnosis was based, not upon clinical manifestations, but upon the presence of the plasmodium in the blood. Dr. Koplik has recently presented an excellent and thorough study of this subject. The ages of my cases were as follows: Six months, eight months, eleven months, two years, three years (two cases), four years, five years, six years (two cases), ten years, twelve years (two cases), fourteen years. In order to bring out some of the clinical features, a few histories will be submitted:

Thomas M., aged five years, 343 East Thirty-third Street, October 11, 1893. No history of any previous illness. Two weeks ago he fell out of a small wagon while playing on the street. This was followed in about two hours by vomiting, and that night he was seized with a fever preceded by chilliness. Since then he has had a fever every other day. He had a chill yesterday, and vomits after the chills. His bowels have been loose and watery for the past twenty-four hours, having had eight movements. He takes nourishment well, but the tongue is covered with a thick white coating. No enlargement of spleen Temperature, 100·2° F.; pulse, 114. Diet regulated and bisemuth and pepsin administered to correct intestinal fermentation.

October 15th .- Gastro-intestinal symptoms improved. No more vomiting and one movement from the bowels daily. The fever ceased for two days, but returned yesterday. Has complained of a cold feeling to-day. On October 16th he had had chilly sensations and on October 17th at 4 P. M. there was a distinct chill, followed by a slight fever. An examination of the blood now showed a few malarial plasmodia. On October 18th he was brought to Demilt Dispensary at 2 P. M. and the temperature was 99.6° F. Almost at once his mother called my attention to the fact that he appeared to be having one of the "cold" turns. Inspection showed the lips and hands to be quite cyanotic, but no rigors. Ten minutes after his first temperature was taken, the thermometer was again inserted under the tongue and found to register 102.4° F. A drop of blood was drawn from a finger during the chill and about half the globules in the field showed malarial organisms. Most of the organisms in the corpuscles showed many pigment spots, but some only one or two. There was a slight enlargement of the spleen. Bowels costive. Quinine, eight grains daily, was ordered.

20th.—Temperature, 98.5° F.; pulse, 100. Yesterday had a very slight chill and fever in the evening. Brighter and better to-day. Quinine continued.

25th.—Temperature normal and appetite good.

29th.-No fever and complete recovery, but ansemic. Qui-

nine stopped. Iron was administered for a few weeks, during which there was no return of malarial symptoms.

Agnes M., aged three years, Third Avenue and Forty-sixth Street, March 20, 1894. The mother had lost three children, two dying of pneumonia during infancy. The third, eleven months old, had an intermittent fever for four weeks, and was said by a doctor in attendance to have died of "malaria." On March 18th, after playing on the street, the child was seized with a high fever, which continued through the 19th, with sweating in the afternoon, upon which the fever abated somewhat. Temperature, 104:5° F., axilla; respiration, 50; pulse, 140. No appreciable enlargement of the spleen. Slight cough. Lungs negative. A blood examination showed the pigmented bodies of the plasmodium with some segmentation. Acetanilide, one grain every three hours, was ordered.

March 22d.—Temperature, 98° F. Fever left upon second dose of medicine. She played around yesterday with no fever. No plasmodium found.

28th.—Temperature, 98° F. Appears well.

April 13th.—Has had no return of the fever, having been perfectly well.

The following two histories show the disease as it occurred in young infants:

Alice C., aged eight months, No. 311 East Fortieth Street, October 24, 1893. Baby is healthy and has always been on the breast. She spent last summer at Mount Vernon, and during the first week in August grew fretful and averse to nursing. After a few days of these indefinite symptoms, she had a chill lasting about fifteen minutes, followed by a fever and cold sweat. Medicine was administered for two weeks, which the doctor said contained quinine, and there was no more fever, but some failure in general health. The mother returned to New York on October 6th, and on October 8th the baby was noticed to get cold for about half an hour, followed by fever and sweating. There was no rigor, as in the first attack. She then had mild daily attacks, but about October 20th the fever grew worse, preceded by a much milder cold stage. The fever appeared to get higher and last longer each day. The baby was very anæmic and iron was given, but no quinine.

October 28th.—Baby no better. Daily fever. A blood examination showed the plasmodium. Quinine, six grains daily, was ordered.

November 2d.—Temperature, 98° F., rectum. No return of fever, but baby is weak and anæmic. Hæmoglobin, fifty-five per cent., and no plasmodium.

14th.—No more fever and much better in every way. Quinine discontinued and iron given.

February 27, 1894.—The mother brings the baby for a slight cold and states there has been no return of any malarial symptoms.

Mary H., eleven months, No. 379 First Avenue, March 22, 1894. The mother has lost three children—one with pneumonia, one with diphtheria, and one in convulsions. The baby is on the breast and healthy, with the exception of certain periodic attacks which began at the age of six months. In them the baby stops breathing, gets black in the face, with eyes open and staring, evidently unconscious, with hands and feet cold. Water is thrown in the baby's face and it comes out of the attack in from twenty to thirty seconds. The mother says a former child had similar attacks, beginning at the age of eleven months. The above account given by the mother points to laryngismus stridulus. The present illness began with vomiting on the evening of March 21st, followed by fever. There are no local symptoms. Temperature, 104° F.; respiration,

48; pulse, 150. An examination of the blood showed the presence of the plasmodium, not abundant, and some eosinophile cells. Acetanilide, half a grain every three hours, was given.

March 24th.—Temperature, 100° F. No more vomiting. Fever broke March 23d. No enlargement of spleen.

27th.—Temperature, 98.8° F. Baby much better. No return of fever. Nurses and sleeps well. Blood shows no plasmodium. Acetanilide continued.

April 13th.—Has had no fever and been well except one or two of the periodic attacks described above.

Four of the cases recovered without the administration of quinine, and a fifth continued well for a week, when it passed out of observation. When the malarial influence is not intense and continuous there appears to be a spontaneous tendency to recovery, in some cases at least. The following history illustrates this point:

Paulina N., aged six months, 489 Second Avenue, January 18, 1894. Five days ago the baby was seized with fever, preceded by cold hands. The temperature lasted two days before abating. To-day she was seized with a fever for the second time. Temperature, 104° F. Plasmodium found. No enlargement of spleen. Small doses of aconite given.

January 19th, 20th, 21st, and 22d.-No fever.

25th.—Blood examined. Eighty-five per cent. hæmoglobin and only one extra-corpuscular plasmodium found.

February 5th .- Blood examined and negative.

15th.—Has continued well, with the exception of a slight cough, until two nights ago, when the hands and feet became cold, followed by a warm skin. She seemed sick the following day. Last night her hands and feet again became cold. Today, temperature 101° F. at 3 P. M. Aconite given.

16th.—No temperature.

17th.—Does not appear very well, but no temperature.

April 13th.—Has been perfectly well since she was last seen at the dispensary. No temperature, but a slight cough.

The statement at the beginning of this paper that paludism is not common in this city is borne out by the fact that these fourteen histories were obtained from a very large number of cases extending over a year and a half, principally at Demilt Dispensary. Six of the cases had recently been brought from malarious districts in New Jersey and Long Island. Dr. Koplik states that in all of his cases decided by the blood examination to be malarial a history of sojourn outside the city limits in the adjacent country districts could easily be obtained.

Almost any bodily disturbance in early life may simulate malaria if one is looking for this condition. In infants and very young children the regular chill is usually replaced by cold hands and feet or a general pinched appearance. The sweat is likewise not marked. The fever is, hence, the principal manifestation, and it is often difficult to establish the sharply marked periodicity noted in the books. Several conditions, some grave and others trivial, are often mistaken for paludal infection. A form of tuberculosis in children, with chills and irregular fever and without marked pulmonary symptoms, presents an appearance closely resembling malaria.

William M., aged eight years, was brought to me with a history of fever and sweating, with an occasional cold stage. There was some cough, and auscultation showed mucous râles at the base of both lungs, but hardly fine enough to account for

the symptoms. Temperature, 103:8° F.; pulse, 138. A blood examination showed hiemoglobin eighty per cent. and no plasmodium. An expectorant only was given. For the next few days he had a chill, followed by fever and sweating at about the same hour—6 r. m. Examinations showed no plasmodium. These symptoms continued about the same for ten days, the daily temperature, when taken, varying from 99.8° to 101:5° F. In spite of treatment the bronchitis seemed to grow worse, with more expectoration, and slight tubular expiration was now noted at the apex of the right lung. An examination of the sputum showed the tubercle bacillus. For over a month this case could have passed for an almost typical malarial attack in the absence of the discovery of the bacillus. Later on, the physical signs alone would easily have established the diagnosis.

I believe a form of intestinal fermentation and catarrh is a condition most often mistaken for malaria in early life. This is accompanied by languor, coated tongue, abdominal or epigastric pain, headache, and a more or less irregular fever, doubtless caused by the absorption of ptomaines. Such symptoms may easily assume somewhat of a periodic type.

Joseph C., aged seven years, was brought February 9th complaining of headache, pains in his limbs, with chills up and down his back and some fever. Sleep very restless at night. No appetite. Occasional vomiting. Bowels alternately costive and loose. February 11th: No improvement and complains of feeling very tired. Blood examined and no plasmodium found. Small doses of calomel, followed by nux vomica and pepsin, with careful regulation of diet, produced marked improvement within a week's time. If such a case is allowed to run on unchecked, anæmia and general prostration produce a similar picture to true malarial cachexia, but dosing with quinine only aggravates the condition by increasing the digestive disturbance. A young child with a certain amount of gastro-intestinal fermentation and insufficiently clad or exposed to cold is very apt to develop subacute rheumatism, with slight inflammation of muscles and fascia and irregular fever, which again may simulate malaria. A certain form of amygdalitis, in which muco-pus forms deep in the follicles, but is seen only as pin points on the surface, may be overlooked upon a superficial examination, and the chills, fever, headache, and constitutional disturbance be referred to malarial influence. The mild typhoid fever that children sometimes contract, true walking cases, with no abdominal symptoms, are liable to be incorrectly treated for malaria. There is a condition often seen in badly cared for children in tenement houses to which the term civic malaria may be applied; but the term is a bad one as implying a paludal infection. A combination of bad food and foul air may easily induce fever and general depression of vitality, but the plasmodium is not found, and quinine has no effect save from a tonic influence when administered in small doses. In making a diagnosis I do not believe that enlargement of the spleen can assume the same prominence in children as in adults. Enlargement may quickly take place from the less resistant quality of the capsule, but the size may as quickly subside. soft texture of the gland renders the enlargement at times difficult to detect. I have not relied upon percussion, but upon deep palpation, placing the right hand below the

twelfth rib on the back, with the fingers of the left hand upon the abdomen, and then bringing them in apposition. The diagnostic value of splenic enlargement in malaria is weakened, inasmuch as it occurs in many diverse ailments of childhood, such as rickets, tuberculosis, syphilis, diphtheria, typhoid fever, and other infections. Before making a diagnosis of paludism, especially in a non-malarial neighborhood, we must make a thorough search for all other possible sources of the disturbance under investigation. We must remember the unstable condition of the vaso-motor centers in early life that renders fever, often irregular and intermittent, a constant symptom of very diverse local and general conditions. I have seen chills and fever from an otitis media in a child who complained more of his head than his ear, although an examination of the latter organ showed the tympanic membrane to be bulging, and a small incision, of course, relieved all symptoms. Quinine would have done much damage. If a careful and prolonged search does not settle the question, the diagnosis must finally rest upon an examination of the blood for the plasmodium. In order to learn the comparative frequency of true malaria in children and adults in places where it is seen oftener than in this locality, I wrote to Dr. William Osler, of the Johns Hopkins Hospital, Baltimore, who kindly sent the following reply: "Paludism is not very common here in children as compared with adults. Our statistics in the wards are as follows: Of the two hundred and forty-eight cases of malarial fever definitely determined to be so by blood examination, there were seventeen cases in children. The youngest case was a suckling aged two months who had it very severely and nearly died. The majority of the cases were quotidians or tertians, a few of the æstivo-autumnal form. We have no experience of the spontaneous cure of paludism in children; on the other hand, several of our worst cases have been allowed to become chronic. Splenic enlargement was present in all of the cases. We have learned to place more and more reliance, year by year, upon the blood examinations as the only positive criterion in the diagnosis of the disease. Obscure malarial influences we do not recognize specially." In making blood examinations I have had the kind assistance of Dr. Doty and Dr. Menzies at the Demilt Dispensary, and Dr. Brooks at the laboratory of the Postgraduate Hospital.

# THE RELATION OF EYE-STRAIN TO CERTAIN FUNCTIONAL NERVOUS DISTURBANCES.\*

BY FRANK H. BARTLETT, M. D.,

Ir has frequently been said, and perhaps in many instances with good reason, that specialists in medicine, particularly those interested in the development of some special theory, are inclined to be one-idea men. Everything connected with the practice of their profession is narrowed down to conform to that particular line of thought in which

 $<sup>{\</sup>bf *}$  Read before the Medical Society of the County of Cattaraugus, February, 1894.

their minds happen to be directed. The over-enthusiastic oculist, always looking to the eye for the cause of all ills that flesh is heir to, examines his patients with this one idea in mind; and, expecting to find some defect which will account for the symptoms complained of, will, I am bound to admit, in nearly every instance discover something which, in his opinion, warrants him in assuring these patients that a properly adjusted glass or a few tenotomies will afford certain relief. An equally zealous gynæcologist may perhaps examine some of these same cases, and will almost invariably find some disturbance of the pelvic organs which he thinks warrants him in informing the patients that they need look no further for the cause of their troubles, and that a course of treatment, extending over a period of perhaps a few months or years, will certainly result in a perfect cure. These same enthusiasts frequently meet with cases in which they discover ocular defects of high degrees or extensive pelvic disturbances; and yet such patients do not complain of any of the various symptoms usually expected to accompany these conditions. They find in these cases a condition of affairs often difficult to reconcile to their pet theories, and in some instances can only account for it by the conclusion that these patients, by their apparent lack of appreciation of what is required of them, are depriving themselves of their just proportion of the enjoyment of poor health.

On the other hand, there are in the profession men who, perhaps, at some time have seen a few cases in which a pair of glasses, the tenotomy of an ocular muscle, the repair of a cervix, or the removal of an ovary have failed to afford any appreciable relief, and from their knowledge of these few isolated cases allow their prejudices to carry them just as far to the opposite extreme, and take the position that in spite of the fact that abundance of proof to the contrary can be brought forward, the whole subject is utterly devoid of reason in theory and of no possible value in its practical application.

These, gentlemen, are the two extreme positions taken by different members of the profession in the investigation and discussion of nearly every new idea brought forward for consideration; and such will probably always be the case so long as the world moves. I believe, however, that no subject of sufficient importance to provoke any extended controversy between men in these extreme positions is without a certain amount of true value, and that there is a middle ground from which such subjects can be viewed, letting cool, sober judgment take the place of the perhaps too extravagant views of the enthusiast or the unconquerable prejudices of the pessimist; and from this standpoint much sound reason in the theories will be discovered, which, intelligently applied, will bring about satisfactory results.

I am fully aware that in certain points the subject to which I direct your attention is a matter for controversy between members of the profession; also that so much already has been written in regard to it that whatever I may have to say may seem superfluous; still, I trust that a short time can be devoted by this meeting to the consideration of the subject of eye-strain and its relation to certain

c II:

a. J

functional nervous disturbances, with a certain amount of profit to the writer, at least, if to no other person who has grace given him that will enable him to sit quietly through the entire reading of the paper.

In practice we all meet with cases who come to us complaining of headaches, disturbances of the digestive apparatus, insomnia, inability to perform their accustomed duties without great effort and fatigue, or of many other kindred symptoms for which we can assign no direct cause. In some of these cases marked hysterical symptoms may be manifested, the patient being thrown into a state of extreme nervous excitement from slight causes.

We generally find such patients to be much below par as regards general nutrition and the power of endurance. After examining them carefully, and finding no evidences of organic disease, we prescribe tonics, etc., advising, perhaps, systematic nourishment and exercise, and in connection with these complete mental relaxation, expecting that a persistence in this plan of treatment will, after a reasonable time, bring about satisfactory results. Many of these cases may respond to this treatment to our entire satisfaction, but in a large proportion of them we are disappointed at the results. Many of them show no progress, and others, while seeming to improve for a time, show a disposition to drop back to their original condition from slight causes or any relaxation in the systematic course of treatment which is being employed. In fact, there seems to exist in these cases some adverse influence which greatly lessens their powers of endurance and the ability to accumulate that supply of reserve nervous energy necessary to provide for occasions of extraordinary mental or physical activity. In other words, the ordinary demands for energy in these cases are as great, or greater, than the supply. This adverse influence, whatever it may be, makes unusual demands upon the nervous system, and consequently, by diverting from different organs their normal supply of nerve force, tends to impoverish them, and as a result the proper performance of their functions is very materially interfered with, favoring the development of many functional disturbances.

Now, if the foregoing conclusions are facts that can be demonstrated by experience; if this influence really is present in some cases, and the cause can be located and removed, we at once realize that by stopping this constant drain on the nervous system we restore the natural equilibrium of the different organs, and the patient is now in a much more favorable condition to respond to any plan of treatment that may be employed.

I believe fully that the truth of the foregoing theories has been established by practical experience, and that in many cases this influence does really exist. I also believe that in many cases of the class just described we find in eye-strain, resulting either from errors of refraction, want of equilibrium between the ocular muscles, or a combination of these two conditions, a very frequent cause for these excessive demands upon the nervous system, and a consequent waste of energy, the proper correction of which will in many instances be followed by most gratifying results.

Before proceeding further with the consideration of the

ocular defects which may induce eye-strain, it is important that we understand what is generally accepted as a normal eye.

Perfect binocular vision is dependent upon that condition of the eyes in which the relations between the curvature of the surfaces of the cornea and lens in all meridians, the length of the eyeballs, and the adjustment of the ocular muscles are such that all rays of light entering the eve from a distance beyond twenty feet are brought to a focus at exactly the same point on the retina of each eye, with no effort except that exerted by the ocular muscles in directing the eyes toward the object and fixing them in this position. This movement and fixation of the eyeballs should be accomplished with such an equal distribution of tension that no excessive strain is required of any muscle or set of muscles to overcome undue power exerted by opposing muscles. In other words, normal vision means the ability to see objects at a distance clearly when both eyes are in a state of rest.

Deviations from this theoretically normal standard are of great frequency, and, within certain limits, may exist with no apparent ill effects. The question as to how great the departure from this standard must be to produce evidences of eye-strain is one much discussed at present and will probably never be settled, some oculists correcting the slightest defects discovered, while others believe that a considerable degree of error can be ignored without inconvenience to the patient.

It would seem that no definite standard which will guide us in the correction of these ocular defects can ever be arrived at. Each individual case must be studied by itself, taking into consideration the temperament and general make-up of each patient. The correction of very slight defects will in some instances be followed by most gratifying results; while, on the other hand, every oculist not infrequently discovers errors of refraction or muscular insufficiencies of marked degree, and is surprised at the slight annoyance given by them to the patients. Gynæcologists, also, frequently meet with cases of extreme laceration of the cervix or perinæum, or displacements of the pelvic organs, and yet these patients seem to suffer little from them.

As a rule, however, we find such patients to be persons of good physique, full of vital energy, well nourished, having great powers of endurance, and with nervous systems which are not easily impressed by occasions of extraordinary men-· tal or physical activity. Such persons have usually inherited strong constitutions, and the different functions of the organs are performed with such precision that, in the matter of waste and repair, the balance is always greatly in favor of the accumulation of an ample supply of reserve strength or vital energy; and, while the existence of an ocular defect or of pelvic disturbances always necessitates an excessive expenditure of energy, all conditions are so favorable in these cases for the accumulation of reserve force that little or no impression is made upon the nervous system as a result of such demands so long as a condition approaching perfect health continues. Let such a person, however, become debilitated by a protracted illness, or from

any cause that will result in great loss of vitality and general muscular strength, then these reflex symptoms, which so often accompany and are induced by eye-strain or pelvic disturbances, will in very many instances manifest themselves; and, furthermore, particularly in the case of eye-strain, while such a person may seem in every other respect to have regained his former strength, these evidences of eye-strain will persist, he now having lost the ability to overcome this trouble, which before this illness he could do with apparent ease.

The persistence of these symptoms of eye-strain in such cases can perhaps be better understood when we remember that, where certain ocular defects exist, the eyes are under a constant strain every moment when not closed, and little opportunity is afforded the ciliary or ocular muscles for rest or the regaining of their former strength. To the other muscles of the body, on the contrary, many opportunities for rest are afforded during the day, either by a complete relaxation at different times of certain muscles, or being relieved of a portion of their work through the combined action of other muscles at times when overtaxed. A large proportion of the cases that come under the observation of an oculist present conditions quite the opposite of those just referred to.

Many of these patients come for treatment, referring their troubles directly to the eyes, and yet in very many instances examinations reveal but slight defects. The correction of these slight defects, however, frequently affords relief beyond expectation. We usually find in these cases conditions as regards strength and endurance quite different from those observed in the type we have just considered. These patients, as a rule, are never robust, seem poorly nourished, and have inherited nervous temperaments highly sensitive to slight impressions. The accumulation of strength in these cases at best barely meets the ordinary demands of life, and, as a consequence, their powers of endurance under favorable circumstances being limited, they find themselves unable to meet those inevitable exigencies of life which call for an extraordinary expenditure of mental and physical energy, without not only utilizing all surplus strength, but, in addition to this, so to speak, drawing on the future; and, as a result, when the occasion is past, they find themselves in a condition of exhaustion from which it may require days or weeks of rest to recover.

In these cases, the patients having no surplus strength from which to draw, an excessive demand for energy in any particular direction can be met only by diverting to this purpose more or less of that normal supply of energy which should at all times be given to the different organs and is necessary for the maintenance between them of a perfect equilibrium in the performance of their various functions. Should this excessive and unnatural outlay of strength or energy in any direction (though it may for a time seem of little importance) continue for any extended period, its evil effects will manifest themselves by evidences of an improper performance of these functions, by reason of the continued withholding from various organs of their normal stimulus. Thus the facilities for generating nerve force gradually be-

come lessened, and the result is a general lowering of vitality. The resources for strength are now never quite equal to the usual requirements, and there exists a condition of affairs extremely favorable for the development of any or all of the neurotic disturbances generally known as functional nervous diseases.

Having, as I trust, made myself clear on the foregoing points, I am now led to the proposition that eyestrain will in many cases induce or at least contribute toward the development of functional disturbances, and that the conditions most favorable and perhaps necessary for their development are an impressionable nervous temperament and a want of resistance in the individual in whom ocular defects may exist.

It is not my purpose at this time to go into a detailed description of the different visual disturbances which are known to induce eye-strain, nor do I wish to weary you by presenting statistics bearing upon the subject. I simply desire to call attention in a general way to some of the most important of these defects, devoting only sufficient time to them to establish the fact of their possible relationship to this subject of functional nervous disorders.

The more frequent causes of eye-strain are perhaps hyperopia and astigmatism. In hyperopia, as you already know, the eyeball being too short or the cornea and lens too flat, parallel rays of light can only be focused upon the retina by bringing into action, by means of the ciliary muscle, what is known as the power of accommodation. This, in a normal eye, is only brought into action at such times as the eyes are used for near work or looking at near objects. At all other times, when directed toward distant objects, the eyes (if perfect) should be practically at rest. The vision of a hyperopic eye, if the defect be of not too high a degree and the patient not over forty or forty-five years of age, may be normal; but perfect vision with such an eye can only be maintained by calling into requisition at all times this accommodation, thus subjecting the eye to a constant strain; and we can readily see that a much greater strain must become necessary for near work. Such an eye can never be at rest, the ciliary muscle being brought into action at all times both for near and distant

In astigmatism we find a variation in curvature of the different meridians of the cornea, and as a result rays of light entering the eye at these different meridians can not be brought to a focus at the same point. Distant vision in an astigmatic eye is usually more or less interfered with. A certain amount of astigmatism, it is believed, can be overcome by the action of the ciliary muscle; but in cases of more than a very slight degree no action on the part of the eye can to any extent improve the vision. In astigmatism a clear-cut image of an object is at all times impossible, but there is on the part of the eye always an unconscious effort to get better vision. This effort, together with the nervous disturbance caused by the blurred image, keeps up a constant strain, greatly increased in near work.

In our description of a normal or ideal eye perfect condition of the weaker remains about as before, thus rebinocular vision was made one of the conditions necessary for perfect eyesight. This can only be accomplished by an of these muscles when the prism is removed. We find in

equal distribution of tension, so that at all times an accurate fixation of the eyeball may be maintained with such a perfect balance between different ocular muscles, or sets of muscles, that no excessive strain will be put upon any muscles because of undue strength in those that oppose them. In all cases in which there exists a lack of this proper balance between ocular muscles the eyeballs tend to turn toward the stronger muscle, and in instances where a very great departure from a normal balance is present the deviation amounts to a marked squint. It is not to these cases of decided squint that we refer, however, in speaking of the relations of muscular insufficiencies to eye-strain. for we must remember that in such cases the patient, while fixing with one eye, is able to suppress the vision of the squinting eye, thus avoiding very distressing double vision, which would otherwise exist at all times.

The insufficiencies causing symptoms of eye-strain are those in which either the deviation is just sufficient to cause diplopia, or double vision is only avoided by an excessive effort on the part of the weaker muscles. In such cases confused vision results, or objects are only seen distinctly by imposing a constant unnatural strain on the weaker muscles, and, as in the case of refractive errors, the result is a great waste of energy.

Errors of refraction can only be corrected by the adjustment of a proper glass, and while there exists a considerable difference of opinion among oculists as to how great the error must be to require correction, I believe that all agree that these conditions in a very large percentage of cases cause eye-strain, and certain reflex symptoms may follow as their result. In regard to insufficiencies of the ocular muscles, however, there is a much greater diversity of opinion, some believing and teaching that all muscular insufficiencies should be ignored, while others, representing the opposite extreme, believe that in these muscular defects they find a cause for nearly all nervous reflex symptoms. This question is one which it seems to me should be investigated from this middle ground before referred to, and I believe that many of our conservative men of to-day are finding that a large number of cases which have heretofore received little or no benefit from simply the correction of refractive errors are being greatly relieved by treatment directed toward these muscular insufficiencies.

The correction of insufficiencies of ocular muscles, if of but slight degree, may be brought about by the adjustment of prisms (the base of the prisms placed over the weak muscles, taking off a certain amount of strain from those muscles). Prisms, however, have no curative effect, and do not tend in any way to strengthen weak muscles. They usually must be constantly worn if relief from their use is to be expected. In fact, the manner in which the strain is taken away from a weak muscle by a prism is by so bending rays as they enter the eye that more work is put upon the opposing muscles, and if worn constantly the tendency is toward an increased development of strength in the strong muscle by reason of its increased exercise, while the condition of the weaker remains about as before, thus resulting in a still greater difference in the relative strength of these muscles when the prism is removed. We find in

practice, however, notwithstanding this tendency just referred to, that in many cases weak prisms are worn by patients year after year, giving perfect relief, or in some instances after having by their use afforded weak muscles a period of rest can be dispensed with, the patient experiencing no further annoyance from the previous trouble. In cases in which the defect is of a high degree, prisms, as a rule, afford little or no relief. Such cases require treatment that will restore the proper equilibrium between these muscles by either strengthening weak muscles or diminishing the strength of such as are manifestly too strong.

This may be accomplished either by a division (or tenotomy) of the strong muscles, or, when the defect seems to be altogether due to a lack of normal power in the weaker muscles, by the operation of advancement of the tendons of these muscles. This operation is done by separating the muscle from its insertion, and so drawing it forward and retaining it in this position by means of sutures, that it will attach itself to the eyeball at a point in advance of its former insertion; thus giving the muscle a much better purchase on the eyeball, thereby increasing its power of rotation.

In what has been written in regard to this subject an effort has been made to avoid, so far as possible, the unnecessary use of technical terms; and I trust I have expressed myself with sufficient clearness to establish in the minds of some who have listened a belief in the possible existence, in some cases at least, of a relation between eyestrain and certain functional nervous diseases.

Before leaving the subject I wish to impress upon you, first, the fact that while in many instances eye-strain may be the direct cause of reflex nervous troubles, ocular defects do not exist in all nervous patients; and furthermore, in many cases, even if discovered, little or no relief will result from their correction. In such cases we must look further for the cause of the difficulty. I am firmly convinced, however, that the facts at my command warrant me in the statement that in no case manifesting these nervous symptoms which has failed to respond to ordinary treatment, employed for a reasonable period, is the investigation complete until an examination of the eyes has determined as to the presence or absence of ocular defects; and should such defects be discovered, all indications for proper treatment have not been fulfilled until they have been corrected.

It must also be borne in mind that the treatment of these cases does not end with simply the adjustment of glasses or the performance of a tenotomy; as has already been intimated, the relief of eye-strain, by stopping one of the leaks through which much energy is lost, places the patient in a much more favorable situation than before for responding to appropriate treatment directed toward the improvement of general nutrition and the accumulation of surplus strength. My observation in a number of cases of this class has led me to believe that in the general treatment of these patients more favorable progress may be expected if less reliance is placed on medication and more attention given to a liberal supply of nourish-

ment, plenty of rest, mental relaxation, and, in connection with these, a judicious amount of regular systematic exercise.

The over-enthusiastic theorist will doubtless meet with many disappointments in this matter of eye-strain; but I am thoroughly convinced that the combined experiences of those now interested in its investigation will bear me out in the assertion that while the correction of ocular defects will not in every one of these neurotic cases result in a perfect cure, a very large proportion of them will be afforded sufficient relief to fully repay both patient and physician for all time devoted to this subject.

## THE TREATMENT OF HÆMORRHOIDS.\*

BY CHARLES B. KELSEY, M.D.

In the discussion of a question such as this, clinical fact is of so much more value than any theories, that I must ask pardon in advance for confining what I have to say almost entirely to the report of personal experience.

At the clinic for diseases of the rectum at the New York Post-graduate Hospital the following advantages are claimed with some positiveness for the clamp and cautery operation over all other methods for the radical cure of hæmorrhoids:

- 1. The least pain.
- 2. The quickest recovery.
- 3. The least vesical and general disturbance.

That the results as to radical cure and safety from every sort of accident are fully as good as after the use of the ligature has been so often proved, and is at all times so easily capable of proof, that here it need only be touched upon. My personal experience with the operation extends over about ten years, during which I have used it exclusively without ever having had a serious accident or complication of any sort. A single case of failure to cure, or of secondary hæmorrhage, or of any grave accident which could be attributed to any defect in the operation itself, and was not equally liable to occur with any other method of treatment, would have caused its abandonment and a return to the ligature long ago. But there have been no accidents, and the results have invariably been so satisfactory as to leave nothing to be desired.

This statement is made simply to offset the statement made by Allingham years ago, that the clamp and cautery is at least six times as fatal as the ligature—a statement frequently repeated, as often challenged, and for which neither of the Allinghams seem ready to furnish any proof, in spite of the fact that when last repeated (by which time the figure had grown to eight instead of six) three public requests for proof appeared almost simultaneously in British journals.

As to whether the three claims made for this operation are justified by facts and are not matters of theory based upon personal preference for one method over another, the results of the method at the public clinic will best show.

For four years and a half it has been the only operation used. During that time about one hundred and fifty cases have been operated upon. There has been no case of hæmorrhage, failure to cure, failure in the wounds to heal kindly, and but one case in which the subsequent use of a bougie for contraction was necessary. In that case the contraction was entirely overcome by the patient himself in a few weeks and the bougie abandoned.

The majority of the patients enter the hospital an hour or two before the operation and are etherized without previous preparation. The bowels are moved by a cathartic forty-eight hours after the operation. The use of an anodyne or of the catheter is equally rare and both are almost unknown. The patients are allowed to dress and be about the house as soon as they please, and this is generally on the third day. Some of them stay in the house till the end of the first week and can be shown to the class at the weekly clinic following the operation. Many of them go out on the fourth and fifth days. Some of them will report as out-patients at the clinic at the end of the second week, and the vast majority are never seen after that date.

My reason for giving the results of public work rather than of private practice, although they are the same, is that the former can be verified at any time by any member of the profession who takes sufficient interest.

My personal experience with the different methods of treating hæmorrhoids may be briefly summarized in the advice given to the students when discussing this question at this clinic, which is as follows:

If you wish to radically cure your patients with the least possible pain, loss of time, confinement to the house, and risk of accidents—use the clamp and cautery.

If you wish to accomplish the same result with no more risk, but with more pain, more local and general disturbance, and longer confinement—use the ligature.

If you wish to take an hour to do what can as well be done in a minute, and gain nothing by it in results—use Whitehead's operation.

If you wish a palliative treatment which is not a radical cure except when sloughing is produced, which is often attended by accidents which will cause great annoyance to yourself and the frequent desertion of your patients, and which is not free from very grave risks—use carbolic acid injections.

In common with the rest of the surgical world I have spent much thought in trying to find some way of radically curing hæmorrhoids which should be surgically satisfactory on the one hand, and free from the fear which the word "operation" always carries to the human mind on the other. My experience with carbolic-acid injections has been the same as that of all other surgeons. When it is radical it is attended by more pain and risk than any of the recognized operations; and when the pain and risks are escaped it is only palliative. But the risks of pain, burrowing, and ulceration can never be eliminated by any use of this method. For many years I have had a chance to note the results of one of the most popular and successful of the irregular practitioners who follow this method, and his results are the same as those of all surgeons of

standing who have ever tried it. Some of his patients are satisfied and sound his praises—many come to me after abandoning his treatment.

To escape the evils of carbolic acid I have made a series of experiments with galvano-cautery puncture which have never been published. My idea was to inflict a definite localized puncture with a hot iron exactly as in former days we used to cure navus of the face in a child with a shoemaker's awl heated in an alcohol lamp. I thought that by this means I could cause a definitely circumscribed and limited slough, and that by enough of these I could destroy the tumor without causing pain enough to confine the patient to his bed or necessitate ether, and without the risk of doing too much which is inseparable from injecting an irritating fluid into a vascular growth.

My experiments have led me to abandon the method. By it I can cure any case of hæmorrhoids, but the total of pain and confinement is greater than by the clamp and cautery. It is only another effort at mercy such as is illustrated by the old saying about cutting off a dog's tail by inches to keep from hurting him.

This, then, is the simple result of my work as a specialist in this disease. If a patient is sufficiently weary of his affliction to allow you to operate upon him you can best cure him by the clamp and cautery operation. If he is not willing to be operated upon you will save yourself much annoyance and him much suffering if you either decline the case or confine your efforts to purely medical means.

THE EFFECT OF EXERCISE UPON THE TEETH.

BY A. HUGH HIPPLE, L. D. S., D. D. S.,

OMAHA.

THE action of the American Medical Association in establishing a dental section, and thereby recognizing dentistry as a specialty of medicine, has not only conferred dignity upon that calling and secured for its practitioners recognition as professional men, but it has also furnished them with an incentive to familiarize themselves with those broad principles that underlie the practice of medicine. On the other hand it has called the attention of physicians to the fact that the condition of the teeth has much to do with the condition of the general system, and patients are nowadays referred by them to the dentist quite as frequently as to the surgeon. But although physicians are beginning to recognize the seriousness of diseases of the teeth, and to impress upon their patients the importance of having them promptly attended to whenever they show signs of decay, the fact that a rapid deterioration of these organs is now going on and that serious results are likely to follow this deterioration has been almost entirely overlooked. A little inquiry and investigation, however, must convince any one that such a change for the worse is taking place. Children rarely have as good teeth as their parents had at the same age, but on the contrary their teeth are often almost hopelessly decayed before the dentures of their parents show signs of impairment. A century ago the city of New York, with a population of about fifty thousand,

had only one dentist, and although much less attention was paid to the teeth then than is paid to them now, there is abundant evidence to show that our forefathers had better teeth than we have. Dr. Hammond tells us that the coming man will be hairless and toothless, and the tendency certainly seems to be in that direction. The conservation of the natural teeth is the end toward which every intelligent and conscientious dentist directs his efforts, but if the quality of the teeth continues to deteriorate the replacement of lost dental tissue must gradually give way to the replacement of lost dental organs. Every physician knows, of course, that this would not be conducive to health, but that medical men generally do not realize how important a bearing the condition of the teeth has upon the health and longevity of an individual is shown by the fact that in examining applicants for life insurance no question regarding the condition of the mouth is ever asked. The teeth may be so badly decayed that the proper mastication of food is impossible, the saliva may be vitiated, the gums and alveoli may be the seat of abscesses that are continually discharging pus, but these conditions do not concern the examining physician. Probably not one in a thousand, in reporting upon the application of a man twenty-five years of age, would think of mentioning the fact that he had lost, say, all his upper teeth and half his lower ones, although after giving it a little thought few would probably care to dispute the statement that the loss of the teeth before the twenty-fifth year will on an average shorten the life of an individual by at least several years. If this be true, no apology is needed for calling the attention of medical men to the dental deterioration that has been referred to, for discussing its probable causes, and for suggesting possible remedies.

In endeavoring to ascertain why it is that imperfect dentures are so common and dental diseases so alarmingly prevalent, it must be borne in mind that although the teeth are vital organs, developed and nourished very much like the other organs of the body, they differ from them widely in susceptibility to disease. While other organs may be delicate early in life and afterward become quite strong and healthy, or vice versa, the teeth, if not impaired by disease, remain the same, with the exception, perhaps, of a slight increase of density as age advances. All the other organs of the body, too, including the bones, are endowed with recuperative powers whereby injuries are to a greater or less extent repaired; but the teeth possess no such attributes, and are apparently governed by somewhat different laws from those that regulate other parts of the animal economy. Teeth that are perfect in form and structure are rarely if ever attacked by decay. It is only where the enamel is defective that dental caries can obtain a foothold. As the teeth are developed early in life, it is during childhood that those influences are exerted which by interfering with their development predispose them to disease, and it is to childhood, therefore, that we must look for the causes of dental deterioration.

Scientists tell us that use and disuse have much to do with the development of organs, and that with the progress of civilization the brain has increased and the jaws have

decreased in size. The wisdom teeth from disuse have degenerated and become rudimentary; the canines, being no longer needed to tear flesh from the bone and do other heavy work, have become smaller and less prominent; the teeth in general have become soft and chalky and very susceptible to decay. This, they say, is the result of the substitution of soft, well-cooked food for that which required vigorous use of the teeth and masticatory muscles, and as there seems to be no likelihood of civilized man going back to primeval methods of preparing food, the inference is that dental deterioration is one of the prices we are obliged to pay for a high state of civilization. But use and disuse not only modify the size and structure of organs when persisted in for a series of generations, but their effect upon the organs of any one individual are no less marked. Tie up an arm so that it can not be used, and the muscles will soon become soft and flabby and will eventually disappear. Lock up a child in a room by itself with nothing to occupy its thoughts, and it will in time become an imbecile. It appears that a certain amount of exercise is essential to the development of most organs. A part when performing work requires and receives more blood than when at rest, and if much work is performed the blood-vessels increase in size and the part is better nourished. That a close relationship exists between development and nourishment, and between nourishment and exercise, is a fact so well known that it need not be discussed here; but so far as the study of the teeth is concerned the principle has been applied to the race rather than to the individual. It is undoubtedly true that what the people of a country eat for eight or ten generations will determine in a general way the size and shape of their jaws and the form and structure of their teeth at the end of that time; but it is probably no less true that what a child eats up to the time he is eight or ten years of age will determine just as certainly what will be the condition of his dental organs for the rest of his life. If the food of the child is such as requires vigorous use of the jaws, the blood supply will be liberal, the parts will be well developed, and the teeth will not be likely to suffer from decay. On the other hand, if the child is fed on soft food, requiring little or no active mastication, the jaws and teeth will be poorly nourished, and the latter at least will be defective in structure. Erupted into the mouth in that condition, no amount of care can protect them from the ravages of decay, which will sooner or later impair their usefulness and mar their beauty.

It must be remembered in this connection that although none of the temporary teeth make their appearance in the mouth until a child is five or six months of age, their crowns are almost fully developed at birth, and that the jaws of a newly born child also contain the germs of twenty-four of the permanent teeth in various stages of development. These permanent teeth do not begin to erupt until the child is about six years of age, but during that time the process of calcification is continually going on. With the first molars, the incisors, and the canines it is well started by the end of the first year; with the bicuspids, at the end of the second year; and with the second molars at about the fifth year. It will thus be seen that between the sec-

ond and fifth years this process of calcification upon which depends the future character of the teeth is in most active Nature intended that during this period the jaws and teeth should be well exercised, and to that end provided the child with a perfect temporary set of teeth, but, as a matter of fact, they are used but very little compared with the other organs of the body. The muscles of the arms, legs, and head are in almost constant use, and are consequently always well supplied with blood. The brain is wrestling with the problems of life as they present themselves, and it too is being exercised and developed. The eve is being trained to examine every object, and the ear to catch the slightest sound, but the teeth are hardly used at all. Nine out of ten mothers feed their children of that age on soft food. Bread made from fine flour, biscuits soaked in tea or milk, meat cooked tender and cut into small bits, with potatoes and other vegetables in such a condition that they require little or no mastication, form the chief food of the little three-year-olds. Not being actively exercised, the teeth and jaws need but a small quantity of blood, and, owing to the imperfect development that results from insufficient nourishment, they are unable to resist the attacks of the pathogenic germs that are always present in the mouth, and which eventually destroy them.

The remedy is in the hands of parents. If they will see that their children, at the earliest possible age, use their first teeth vigorously, they need have little anxiety in regard to the second set. In other words if a demand is created for sound, solid teeth, Nature will be almost certain to supply them. It is by no means difficult to teach children to chew their food. Nothing pleases small children more than to be allowed to nibble a hard biscuit or bite the meat from a bone. Nature prompts them to exercise their teeth in that way, just as it prompts a puppy to spend hours gnawing at a bone which has long since been stripped of its meat. But the average mother, partly, no doubt, out of respect to dainty dresses and wellkept carpets, but more particularly from fear of possible injury to the teeth themselves, objects to the dental calisthenics in which the child would gladly indulge, and thereby unconsciously opposes the efforts of Nature to develop good teeth. Since teeth that are perfect in structure rarely if ever decay, an ounce of prevention in the way of developing healthy dental organs is certainly worth more than a pound of cure after they are diseased, and if parents will supply their children with an abundance of bone-producing food, see that the teeth are kept clean, have them examined and attended to from time to time by a competent dentist, and, above all, have them well exercised by chewing hard food, Nature will do her part, and their children in after years will rejoice in the possession of that almost priceless endowment, a beautiful and complete set of teeth.

## NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co.

Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 16, 1894.

#### MICROBIOPHOBIA.

There can be no doubt that many persons who are fitted by their natural gifts and by the graces they have acquired to lead a sweet and placid life torture themselves and bore their friends most grievously by their abiding dread, and its incessant manifestation, of coming to harm by reason of micro-organisms lodged in or upon one article or another that they are compelled to handle or otherwise come in contact with. They remind one of the fabled old woman who grieved under the gloomy foreboding that her daughter was fated to marry and bear a child that would fall into the fire and be burned to death. Perhaps these persons have a salutary influence also, for their mania must by its very ridiculousness impress not a few of their acquaintances with the idea that the fight against microbes may be carried too far. This we may say without in the slightest degree casting doubt on the germ theory of disease or on the general policy of seeking to destroy or avoid the pathogenic micro-organisms; to asperse that theory or deprecate that policy at this late day would be to shut our eyes to the plainest of facts.

There is one phase of this microbiophobia that we should have been glad to see restricted to its few victims-namely, the fear of danger lurking in the communion cup; but it has at last achieved newspaper notoriety, and has even been treated with more or less consideration in some of the medical journals. We say "at last" because it was temporarily kept at bay several years ago by the failure of a notoriety-hunter to secure for it a hearing in medical circles. Now, however, it comes out not only that a zealous individual has been so impressed with it as to devise a system of separate receptacles for the various communicants, but that in at least one parish in an intelligent community his device has been adopted. It remains to be seen how long the panic will hold sway in that particular parish, and whether or not the fright will prove so infectious as to lead other congregations to declare—as they practically must if they follow in the Rochester people's wake-that there is considerable danger of any of their number being at the same time affected with a disease communicable through the medium of the oral secretions and so uncivilized as to eject anything from the mouth into the chalice. In our opinion, the cry of danger in the communion cup would be simply laughable did it not concern so sacred and holy an office. Certainly the medical profession can not entertain, much less uphold it, at least not until the medical mind reaches such a pitch of narrowness that the Academy of Medicine, for example, will be moved to melt its loving-cup and mold the silver into thimble-cups for the rising generation of academicians, and that, we imagine, will never

happen; and not until physicians grow so inconsistent as to listen with patience to this allegation of danger, and yet go on smiling incredulously when patients aver that their venereal disease must have been contracted in a privy.

#### THE SIGNIFICANCE OF THE VENOUS PULSE.

THE Edinburgh Medical Journal for June publishes a report of a paper read before the Medico-chirurgical Society of Edinburgh by Dr. James Mackenzie. The author divides the venous pulse into two forms, the auricular and the ventricular. The former, he says, presents distinct evidence of the functional activity of the right auricle. In this form there is also a wave due to the ventricle, and as it increases the auricular wave decreases and finally disappears, and thus the ventricular venous pulse is developed. The latter form is a more advanced stage than the auricular, and, as during its development there is a gradual fading of the auricular wave, there is a period when such terms do not sufficiently denote the character of the pulse; but the terms are convenient for descriptive purposes. The ventricular venous pulse appears only when there is organic disease of the heart itself (most commonly in valvular disease). When failure of the heart is functional and not due to organic disease of the valves, the auricular pulse persists to the end. Similar types of pulse may be recognized in the liver. Here the pulse appears only when there is organic disease of the heart.

In many respects, says Dr. Mackenzie, more information regarding the various cavities of the heart can be obtained from the study of the venous pulse than from that of the arterial pulse. Thus, during a cardiac revolution the arterial pulse is in free communication with but one chamber, the left ventricle, only a portion of the time, whereas in the venous pulse the effects of the right auricle during its systole and its diastole may be observed, while the time of the appearance of the ventricular wave gives information regarding the degree of incompetence of the tricuspid orifice. Information may be gathered regarding the exact time of closure of the pulmonary valves, and the persistence of the ventricle in systole for a short time after the outflow through the arterial orifices has ceased may be noted. There is also distinct evidence of the diastole of the right ventricle in the venous pulse. In heart failure the venous pulse affords information of a kind entirely different from that supplied by other means. Its appearance, increase, decrease, and disappearance may give evidences of changes in the bloodpressure quite inappreciable by any signs given by the arterial pulse. While, as a general rule, an increase of the venous pressure implies a diminution of the arterial pressure, that, nevertheless, is not always the case. Although in some cases the disappearance of the venous pulse is a sign of the restoration of the body to a healthier condition, yet in other cases it may precede a fatal termination. In these last cases there is also a failure of arterial pressure. In pulse irregularities no true knowledge of the action of the different chambers of the heart can be obtained except by the study of the venous pulse, and a fellowship in biology was awarded to Mr. Ulric Dahlgren, one

this study, says the author, throws a new light upon the heart's movements, and reveals a variety of them hitherto unsuspected.

#### MINOR PARAGRAPHS.

THE REGULATION OF THE USE OF OPEN STREET CARS.

THERE can be no doubt, we think, that the city board of health took an important step on Wednesday of this week in the direction of guarding invalids against dangerous exposure in open street cars. An amendment of the sanitary code was adopted prohibiting the use of such cars except from June 1st to October 1st, and directing that during the daytime every fourth car on each line shall be a closed car, and during the night every third car.

#### A SANITARY VISIT OF OBSERVATION.

Ir is announced that the city board of health's bacteriologist, Dr. Hermann M. Biggs, sailed for Europe on Wednesday with the intention of visiting various large cities to study their sanitary regulations and their methods of dealing with infectious diseases.

#### ITEMS, ETC.

Infectious Diseases in New York .- We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 12, 1894:

DISEASES.	Week ending June 5.		Week ending June 12.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	3	0	5	2
Scarlet fever	95	9	116	14
Cerebro-spinal meningitis	2	3	1	1
Measles	132	7	117	5
Diphtheria	214	71	208	43
Small-pox		7	12	3
Tuberculosis		0	145	135

The Death of Dr. Middleton Michel, of Charleston, S. C., occurred on Monday, June 4th. The deceased, who was seventy-two years old, was a graduate of the Medical College of South Carolina, but much of his professional study had been done in Paris. During the War of the Rebellion he served as a medical officer in the Confederate Army, and after the war he was an associate editor of the Charleston Medical Journal. The Charleston News and Courier says of him: "He was a physician of high attainments, a teacher of rare ability, a scholar of great versatility, a writer of eminent merit, and a charming gentleman of the old school who, while alive to the demands of the crowding present, was not unmindful of the historic past. He will be missed in professional walks, and in the quieter and sweeter ways of society there will be many to long for the sight of the vanished hand and the sound of the voice that is still."

The British Medical Association will hold its sixty-second annual meeting in Bristol on Tuesday, Wednesday, Thursday, and Friday, July 31st and August 1st, 2d, and 3d, under the presidency of Dr. George Hare Philipson, of Durham. Among the Americans who are announced in the British Medical Journal to take part in the proceedings are Dr. J. J. Chisolm, of Baltimore, and Dr. George T. Stevens, of New York.

Princeton College .- At the recent annual commencement

of the honor men in natural science. Among the honorary degrees conferred was that of LL. D., on Dr. Alfred A. Woodhull, of the medical corps of the army, and that of A. M., on Dr. Austin Flint, Jr., of New York.

Columbia College.—At the one-hundred-and-fortieth annual commencement, held on Wednesday evening, a hundred and twenty candidates received the degree in medicine. The honorary degree of A. M. was conferred on Dr. Landon Carter Gray, of New York.

The Society of Alumni of Bellevue Hospital.—Officers for the ensuing year have been elected as follows: President, Dr. C. C. Barrows; vice-president, Dr. Parker Syms; secretary, Dr. William N. Hubbard; treasurer, Dr. Robert J. Carlisle.

The German Hospital.—Dr. J. W. Gleitsmann has been appointed laryngologist to the hospital.

Opium as a Preventive of Ague.—Moore (Medical Reporter, Jan. 1, 1894, p. 1) insists strongly upon the powers of opium to prevent a malarial paroxysm, citing several instances in which malarial fever has noticeably failed to attack opiumusers in India. This action seems due to the narcotine contained in the opium.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 3 to June 9, 1894:

The following-named officers, having been found by army retiring boards incapacitated for active service on account of disability incident to the service, are by direction of the President retired from active service:

HORTON, SAMUEL M., Lieutenant Colonel and Deputy Surgeon General.

TAYLOR, MARCUS E., Captain and Assistant Surgeon.

Spencer, William G., Captain and Assistant Surgeon.

Upon being relieved from duty at Camp Merrill, Montana, by Wilson, William H., First Lieutenant and Assistant Surgeon, Munson, Edward L., First Lieutenant and Assistant Surgeon, will proceed without delay to Fort Yellowstone, Wyoming, and report to the commanding officer for temporary duty with troops in the National Park during the season.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending June 9, 1894:

Bright, George A., Medical Inspector. Detached from the U. S. Steamer Newark, ordered home, and granted three months' leave.

Marmion, R. A., Surgeon. Detached from the Smithsonian Institution and ordered to the U. S. Steamer Newark.

MCMURTRIE, D., Medical Inspector. Ordered to the Smithsonian Institution.

#### Society Meetings for the Coming Week:

Monday, June 18th: New Hampshire Medical Society (first day—Concord); New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

Tuesdax, June 19th: Colorado State Medical Society (first day —Denver); New Hampshire Medical Society (second day); New York Academy of Medicine (Section in General Medicine); Ogdensburgh, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Coun-

ties of Kings and Westchester (annual), N. Y.; Baltimore Academy of Medicine.

Wednesday, June 20th: Minnesota State Medical Society (first day—St. Paul); Colorado State Medical Society (second day); New York Academy of Medicine (Section in Public Health and Hygiene); Harlem Medical Association of the City of New York; Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); Medical Societies of the Counties of Allegany (annual) and Tompkins (annual—Ithaca), N. Y.; New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

THURSDAY, June 21st: Minnesota State Medical Society (second day); Colorado State Medical Society (third day); New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private)

FRIDAY, June 22d: Minnesota State Medical Society (third day);
New York Society of German Physicians; Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, June 23d: New York Medical and Surgical Society (private).

### Obituaries.

#### ELIJA S. ELDER, M. D., OF INDIANAPOLIS.

Dr. Elder, business manager of the *Indiana Medical Journal*, president-elect of the State Medical Society, and for fourteen years its secretary, died at his home in Indianapolis on May 19th.

Following exposure while on a trip as a guest of the Hancock County Medical Society, an obstinate obstruction of the bowels developed. This difficulty was overcome after some ten days, but peritonitis supervened and quickly brought the end.

Dr. Elder was born at Dillsborough, Ind., on March 17, 1841. His father, Samuel Elder, was a physician. He came of good old revolutionary stock. Moving to Mount Auburn, Ind., he received his elementary education there, gained a teacher's certificate, and for two years taught in the Shelby County schools. For two years he was in mercantile life, and then, in 1863, became United States provost-marshal for Shelby County and assistant marshal for the Sixth District. These positions he held till the close of the war.

He was graduated from the Medical College of Ohio in 1867 and entered practice at Morristown, Ind. He went to New York in 1875, and was graduated from Bellevue Hospital Medical College in 1876.

Dr. Elder was an active and efficient man in all matters pertaining to the interests and work of the profession as a body, He had been secretary and subsequently president of the local society, president of the city board of health, secretary of the State health board, and for many years a most efficient secretary of the State society. While on his death-bed he was elected president of the latter organization. In 1888 he became professor of medicine in the Medical College of Indiana, and in 1890 became its dean. Much of the success of the college in recent years is due to his efficiency in organizing and conducting its business affairs. During the past summer he was medical director of the Grand Army of the Republic reunion in Indianapolis, a position the duties of which he discharged with conspicuous success. Having been not only a good physician but a capable man of affairs, he will be seriously missed by the profession of Indiana.

## Wetters to the Editor.

THE CELLULOID EUSTACHIAN PROBE.

122 WYOMING AVENUE, SCRANTON, PA., June 5, 1894.

To the Editor of the New York Medical Journal: Sir: Recently some of our otologists have been calling at-

Sir: Recently some of our ofologists have been calling attention to the celluloid Eustachian probe. Only last year it was mentioned among new instruments in an otological journal. I have used this instrument for ten years and do not consider it new. I first saw it used by Urbantschitsch, of Vienna. I desire, however, to call attention to the danger of this instrument.

The material of which it is made undergoes a spontaneous change which renders the probe exceedingly fragile; so that in following the curve of the catheter it is liable to break, and the small piece thus broken off is almost sure to be pushed on into the Eustachian tube. This I think would be a more embarrassing accident than the unintentional leaving of a sponge or forceps in the body after a laparotomy.

Whalebone is certainly unsatisfactory, and, if celluloid must be used, these instruments ought to be frequently tested and frequently renewed.

C. L. Frey, M. D.

## Proceedings of Societies

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Third Triennial Meeting, held in Washington on Tuesday, Wednesday, Thursday, and Friday, May 29, 30, and 31, and June 1, 1894.

The President, Dr. Alfred L. Loomis, of New York, in the Chair.

(Continued from page 726.)

Nephritis in its Surgical Aspects.—At a session held under the direction of the American Association of Genitourinary Surgeons, a discussion on Surgical Kidney was opened by Dr. EDWARD L. KEYES, of New York. He confined his remarks to a consideration of that form of surgical nephritis in which suppuration occurred, either spontaneously, in the course of disease of the urinary tract below, or originating below as a result of infection by the surgeon. His paper, in its introductory portion, cited many authorities in support of the following statements: 1. That without microbic infection, suppuration in the kidneys was impossible. 2. That the bacilli found oftenest were notably the Bacterium coli commune, and less often the Staphylococcus pyogenes aureus. 3. That these bacilli gained entrance in a variety of ways. 4. That the introduction alone of these bacilli did not occasion ascending pyelitis or even necessarily cystitis. 5. That the soil was made receptive for microbic invasion by anything which interfered with the free urinary outflow, by traumatism, and by failure of general vitality of the individual. The kidney was especially prepared for invasion by dilatation of the ureters.

Dr. Keyes then described his clinical methods of securing urinary antisepsis and asepsis, and of instituting catheter life upon the old subject, whose bladder, ureters, and kidneys were damaged. Then followed an exhaustive account of bacteriological work conducted for him by Professor Dunham, of New York, to determine the destructive or inhibitive power of va-

rious medicinal agents over these three bacilli. The clinical conditions had been reproduced as nearly as possible in the laboratory. It was found in this way that nitrate of silver was by far the best agent for overcoming the effects of local contamination, while corrosive sublimate was better where the tissues were involved. Salicylic acid was shown to be very useful, while boric acid was proved to be of no more value than common salt. The various medicated urines showed little or no inhibitive power over bacterial growth.

From these researches the author concluded that microbic infection always took place from within the body in the course of disease; that the healthy organism and a vigorous bladder could cope successfully with microbic invasion; that a suitable condition of the patient's soil was necessary for the perpetuation of the inflammatory symptoms after microbic invasion; that this condition was intensified by traumatism and physical weakness, and by a dilated and diseased condition of the ureters and kidneys; that pyelonephritis under these circumstances was most often the result of microbic infection from below; and, lastly, that by local means principally, and by flushing the urinary passages with mineral waters, asepsis and sterilization of the urine could best be attained.

The Bacteriology of Pyelonephritis. - Dr. George M. STERNBERG, surgeon general of the army, in a paper on this subject, said that ascending nephritis or pyelonephritis was very commonly secondary to a cystitis of long standing. Recent researches showed that the Bacillus coli communis was found more frequently than any other micro-organisms in the so-called "surgical kidney." This bacillus was now known to be the usual cause of peritonitis. Injections of a pure culture into the ureter, after tying it below the point of injection, had been shown by Schmidt and Aschoff to give rise to pyelonephritis, and the changes so induced were said to be those seen in the "surgical kidney" of man. Clado, in 1887, Albarran and Hallé, in 1888, and Rovsing, in 1890, had described non-liquefying bacilli, found by them in the urine of patients with chronic cystitis or pyelonephritis, which appeared to be identical with the Bacillus coli communis, which had been shown by the subsequent researches of Schmidt and Aschoff, and of others, to be very variable in its growth on various culture media. Krugius, in 1891, had first identified the bacillus described by Clado (his Bactérie septique), and by Albarran and Hallé (Bacille pyogène), with Bacillus coli communis, and this identification had been verified by the researches of Achard and Renault, Schmidt and Aschoff, and others. In twenty-two cases of cystitis studied by him in 1892, Krugius had obtained Bacillus coli communis fourteen times in pure cultures. Relaub, in 1892, had obtained the same bacillus in pure cultures in six cases out of sixteen of cystitis examined. The number of cases of pyelonephritis reported by various authors since 1889 in which Bacillus coli communis was found, and in which it was probably the cause of the ascending nephritis, was twenty-nine, and in twenty of these it had been found in pure culture. In view of these facts, the ætiological relation of this bacillus to ascending nephritis seemed extremely probable. Certain cases appeared to be due also to the presence of one or more species of Proteus, and possibly there were some due to other micro-organisms.

Dr. George Chismore, of San Francisco, continued the discussion. He said that the conclusions he had drawn from his own observations tallied quite closely with those expressed in the paper. It had seemed to him, however, that a small stone, growing slowly in the bladder, apparently established a tolerance in the viscus, and also that the introduction of an instrument into the bladder of a young subject was more apt to be followed by renal complications than when the subject was older. He agreed thoroughly with the author as to the danger

being greater when there was polyuria with the urine of a low specific gravity. Tubercular affections of the urinary tract exerted a similar prejudicial influence. He had never believed that injections into the bladder could be effectual in destroying the microbes.

Dr. Francis S. Watson, of Boston, spoke of the effect of long-continued drainage of the bladder in relieving the form of pyelonephritis under discussion. He could recall six cases in his practice which had exhibited marked benefit from such treatment. Two of these had been treated by a catheter passed in from the meatus, and four by the use of a soft-rubber tube in a perineal opening. The treatment was most applicable to old prostatics in whom the disease was already marked. No one need hesitate because of the acuteness of the symptoms.

Dr. Keyes said that he had practiced this method of drainage with satisfaction.

The Conservative Surgery of the Female Pelvic Organs was discussed at a session held under the direction of the Amer ican Gynæcological Society. Dr. William M. Polk, of New York, opened the discussion. His remarks were based on a hundred and sixty-four cases of abdominal section for disease of the appendages. Of these, sixty-four had been subjected to the radical operation, and one hundred to the so-called conservative process. Among the three prominent operations on the uterus-viz., myomectomy, ligation of the arteries for fibroma, and curettage and packing-the first might be said to be particularly appropriate in all cases of pedunculated fibroids, fibrocystic or myomatous growths; ligation of one or more of the feeders of the uterus instead of oophorectomy; and curettage and gauze-packing in all forms of endometritis. To avoid the occurrence of premature atrophy of the genital organs in young women, and to retain the function of ovulation, he had practiced, and with success, resection of the diseased ovaries.

In conclusion, he referred briefly to a number of his cases in which pregnancy had followed such conservative operations, and, more important than all, where the mental, moral, and physical well-being of the patients had been preserved.

Dr. William Goodell, of Philadelphia, being too ill to continue the discussion, his paper was read by the secretary of the Congress, Dr. William H. Carmalt. In this paper the writer stated that he considered that the whole question of the proper treatment of these disorders hinged on the effect of castration on women. These effects were prolonged and distressing vasomotor disturbances, a tendency to low spirits, suicidal impulses, and even insanity. Again, castrated women were liable to become unsexed to such an extent as to lose all sexual feeling or to have it greatly blunted. In some, senile atrophy of the genitalia took place, or in its place there was a hyperæsthetic condition of the vulva which forbade coition and created much domestic unhappiness. An unavoidable and disagreeable result from castration was sterility, which in itself was often a curse. The writer laid stress on the prevalent lay opinion that women deprived of their ovaries were thereby wholly unsexed. Castration in the male or in the female was alike regarded as a sexual mutilation to which a stigma was attached. No woman would marry a eunuch, and few men would wed a woman without ovaries. It was manifest, he said, that during the period of a woman's menstrual life her mental, physical, and social welfare depended largely upon the continuance of the catamenial and reproductive functions; hence, the conservation of those organs which presided over these functions was of the utmost impor-

The writer went on to deprecate hasty operative interference. According to his experience, few women perished from chronic disease of the pelvic organs; many more died from radical operative measures. Cases were cited in which great

disorganization of the tubes and ovaries had not prevented conception, and also where pregnancy had occurred even when only a small fragment of the ovary or a short stump of tube had been left after the operation. The writer contended that the glory of modern surgery was conservation, yet the glamour of antiseptic surgery had so dazzled the modern gynæcologist as to make him a spoiler rather than a conservator.

Dr. Luteaud, being asked to take part in the discussion, said that he had never seen Dr. Polk's method of curettage and packing cure a case of pyosalpinx, but he had seen pregnancy follow this conservative treatment. He was decidedly of the opinion that a woman under forty years of age enjoyed much better health when the function of menstruation and ovulation had not been interfered with.

Dr. Matthew D. Mann, of Buffalo, expressed his pleasure at having heard this discussion, for he believed it would have the effect of removing the stigma from the gynacology of the present day—that there was too strong a tendency to do mutiating operations. He had practiced Dr. Polk's methods, and had had his patients express their gratification at this conservative effort.

Dr. Joseph Taber Johnson, of Washington said that in one sense all were conservative. He thought the radicals would not accept the statement that they believed in the total destruction of woman's genital organs and the crowning glory of womanhood—motherhood. He did not know of any operator who cut out the ovaries for the cure of a salpingitis, or removed the tubes for a slight inflammation and where the tube was still open. Most of the patients operated on had already been made sterile by the disease. He was afraid that the discussion would have the effect of deterring many from submitting to operation who really needed such treatment.

Dr. Howard A. Kelly, of Baltimore, said that we were unfortunately at a stage when we were obliged to speak of these matters in a sweeping way, instead of referring to special forms of pelvic disease. This discussion had begun ten or eleven years ago, when the question had arisen as to the propriety of removing both ovaries when only one appeared to be diseased. It had not long ago been the practice to remove an ovary containing a small cyst, yet now it was his practice to rupture even quite large cysts without extirpating the ovary.

Dr. Florian Krug, of New York, said that he belonged both to the radical camp and to the conservative camp. He was in accord with most of Dr. Polk's statements.

The Influence of Animal Experimentation on Medical Science.-The president's address, on this subject, was delivered on the evening of May 31st. In the address it was said that medicine had been persistently denied a place among the sciences, yet to it alone the answer "We do not know" had been denied. The scientific experimenters sought for truth and truth alone. In widespread epidemics the effect of disease might be studied on vast numbers of human beings and with great sacrifice of human life; but in the laboratory great truths were discovered with but small loss of animal life. Galen had laid the foundation stone of medical science, yet little besides the experimental part of his vast labor had stood the test of modern scientific investigation. From Galen's time to Harvey's great discovery of the circulation of the blood, very little experimental work had been done, and medicine, instead of advancing to the position of an exact science, had become the plaything of theorists and impostors.

After Harvey, the next series of epoch-making experiments had been made by Galvani and Volta on the condition of the nerves and muscles. The first attempt to continue life for any length of time by means of artificial respiration had been made by Robert Cook, in 1664, and this method was now the reco

nized means of preserving life in cases of asphyxia and in resuscitating the newborn. Boyle, near the close of the seventeenth century, had demonstrated that atmospheric air was necessary to animal life. Dr. Christopher Wrenn, of Oxford, had been the first to make experiments in injecting substances into the blood-vessels, and in 1666 the first transfusion of blood had been tried on animals. Mr. Boyle had afterward elaborated this method, and had shown that death from hæmorrhage might be prevented by the transfusion of blood.

The investigations of Magendie on living animals had inaugurated the great work of the present century. We might rightly regard him as the originator of the modern system of animal experimentation.

The speaker said he would call the special attention of the opponents of animal experimentation to the fact that in all this list of investigations not a single experiment had been directed immediately to the discovery of disease, but solely to the determination of the physiological function and normal action of the vital processes, and to defining the specific influences of given substances on the healthy living organism. It had not been until Claude Bernard had applied his experimental methods that the action of medicinal agents had been well understood. By such experimentation modern therapeutics had been emancipated from the bondage of empiricism, and no longer wounded friend or foe by aimless blows in the dark. It was worthy of note that all these various investigators were working in one direction—the relief of human suffering. The anæsthesia of chloroform had been discovered through experimentation on a low form of animal life-the ant. The illustrious Simpson had perfected his experiments in the use of chloroform on animals before trying it on the human subject. Hypodermic medication had been used on sporting dogs before it had been tried on the human being. By laboratory experiment it had first been proved that tuberculosis was an infectious disease. The valuable studies of Pasteur had introduced us into a new and strange world, and his methods of experimentation had been imitated by experimenters all over the world. The crowning glory of Pasteur's work had come with the discovery of the attenuation of viruses.

The discovery of the bacillus of tuberculosis by Koch had marked another great epoch in medical history, but it had only been accomplished by a continuance of Pasteur's methods of animal experimentation. Within the past two decades animal experimentation had accomplished more in the field of cerebral localization than all the previous centuries of post-mortem study. Looking back over this history of medical discoveries, it was evident that most of them had been barren of immediate results. The fatal error of the opponents of animal experimentation was that they demanded immediate results. The only ethical question was, What price should be paid for the benefit received? Did the end justify the means? In answer to this we could seriously appeal to all intelligent men for a just criticism; from the ignorant we need expect only censure. But from those who, in the valley of the shadow of death, had learned what manner of men we were we could confidently expect the answer, "We have trusted to you the lives of our dear ones; we trust to you God's dumb creation."

#### PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of April 11, 1894.

(Concluded from page 700.)

Acute Puerperal Cellulitis and True Pelvic Abscess,-Dr. Charles P. Noble read a paper with this title in which he stated that it was his purpose to report his experience with

acute puerperal cellulitis and true pelvic abscess, collecting together in one paper the various cases which he had reported from time to time. The time had now come when such a communication would be received in a proper spirit-that is, as a report of conditions carefully observed at the bedside, and therefore as a contribution to scientific medicine. The first whirl of excitement which had followed the discovery of the real nature of chronic pelvic inflammatory troubles had passed by. Men were no longer blinded by the prejudices of the era when all pelvic inflammation had been regarded as cellulitis. A sufficient time had now elapsed to enable them to recover from the reactionary wave, during the height of which it had been believed that all pelvic inflammation had necessarily been tubal in origin. Practitioners of medicine were very prone to be ruled by the dogmas of a few leaders in professional thought, and gynæcologists were no exception to this rule. During two generations they had given implicit adherence to the dogma of Nonat, Churchill, and Emmet, and during the present generation no less implicit adherence to that of Tait and his disciples. It was now time to accept all the facts in the case, whether or not they agreed with prevailing theories.

CASE I .- Dr. Noble had seen this patient operated upon on May 8, 1888, by Dr. D. Longaker, who had given him the following history: Mrs. F., aged twenty-six years, tertiipara. She had been delivered of the third child seven weeks before by a natural and easy labor. On the fifth day she had had a chill, and chills and fever had continued thereafter, also great pain. Dr. Longaker had seen her seven weeks after labor, and had operated for a clearly defined mass situated mostly in the left side of the pelvis, rising up above the brim of the pelvis and extending from the symphysis pubis to the iliac crest. An exploratory colliotomy had shown that both uterine appendages were of normal size, but were somewhat fixed by recent adhesions; "neither right nor left ovary nor tube formed any part of the mass; these structures could be distinctly outlined apart from it." Fluctuation was distinct in the swelling as had been ascertained by the intra-abdominal finger. A second incision had been made above Poupart's ligament, and about half a pint of pus had been discharged. The pus cavity had been located in the left broad ligament, and had extended between the uterus and bladder into the right broad ligament. The patient had made a good recovery, but had borne no children since. This was probably because effectual means had been taken thereafter to prevent conception.

CASE II.—This patient had been seen at the Philadelphia Lying-in Charity during his service there as senior assistant physician. He was unable to find any published notes of the case. His recollection of its salient points was very clear and distinct. This patient had been infected after labor, and after a number of days had presented the usual evidences of suppuration, together with the signs of intense inflammation in the right side of the pelvis and in the right inguinal region. A hard mass of exudate had formed in the right groin, which could be distinctly outlined by palpation. There had been every evidence that this had been a case of true pelvic abscess, but, influenced by the teaching that all pelvic suppuration was intra-peritoneal, an abdominal section had been made by Dr. Charles Meigs Wilson, assisted by himself. The uterine appendages had been carefully examined, and it had been evident that the pus accumulation had been entirely distinct from them, and that it had been external to the peritonæum. The abdominal incision had been closed and the pus let out by an incision made above Poupart's ligament, near the anterior superior spine of the ilium. This patient had made an uninterrupted and quick recovery.

Case III .- This case was seen by Dr. Noble in consultation

with Dr. Himmelwright, on March 2, 1890. The history, as given to him by Dr. Himmelwright, was as follows: The patient had had a miscarriage on January 3d, in the second month of pregnancy. One week later symptoms of pelvic inflammation had appeared, and a diagnosis of peritonitis had been made. The patient got about by February 1st. After a week, pain had been felt in the right inguinal region, and had gradually increased in intensity, extending to the lumbar region. After another week (February 15th) she had been unable to walk erect and to put her foot firmly on the ground, but had to stoop forward. During this time the temperature had remained normal and there had been no chills. At times the pulse had been slightly accelerated. The pain had continued to increase, and, on February 27th, a swelling had been noticed in the right lumbar region. On March 1st, the temperature had risen to 101° F., and the pulse to 120, and there had been slight chills. On March 2d he had seen her. The temperature was normal, the pulse about 90. The right inguinal region was tender, suggesting, indeed, appendicitis, but there had been no symptoms to warrant the supposition. A semi-fluctuant swelling had been found in the right lumbar region. The next day this swelling had increased, and a hard mass had been felt in the right inguinal region, extending as high as the ribs. The swelling in the lumbar region had been opened and two or three pints of pus had escaped. Introducing his index finger, it had passed around the ilium into the iliac fossa. A rubber drainage-tube had been introduced, and irrigated daily with a dilute solution of peroxide of hydrogen. This discharge had gradually decreased and the tract had healed rapidly, closing from the

It might be asked, the speaker continued, Why was this claimed as a case of true pelvic abscess? The abscess had been undoubtedly situated in the false pelvis on the right side. He had had his finger in it. The entire absence of bowel symptoms excluded perityphlitis. The fact that, on examination, the uterus had been found movable and the broad ligaments free from exudate—no fixation of the appendages—excluded pyosalpinx. Hence, he took it, the abscess had been due to the breaking down of an infected pelvic gland situated behind the peritonæum, in the right iliac region.

Case IV.—This case had been in every way similar to the He had seen the patient, in consultation with Dr. Langrehr, five weeks after labor. The perinæum had been torn, and had been sutured some hours after labor. Septic infection had occurred, and for three weeks the temperature had ranged between 100° and 103° F. During this time there had been no pain or distention of the abdomen, or tenderness of the uterine appendages on examination. The perineal wound had become inflamed, however, and the stitches had been removed. ing the fourth week all the symptoms had abated. At the beginning of the fifth week the fever had increased and tenderness in the left inguinal region had become marked. Purulent matter had been discharged per vaginam, but whether or not it had come from the abscess which had formed was questionable. On examining the patient five weeks after labor, he had found her much depressed, in a typhoid condition, with a swelling above the pubes and to the left. On examination under chloroform anæsthesia, a mass of exudate had been felt in the left broad ligament extending between the uterus and the bladder, and plainly palpable above the pubes. His diagnosis had been true pelvic abscess. He had advised median section for an absolute exclusion of complicating pyosalpinx; then a second incision parallel with Poupart's ligament, to evacuate the abscess. This had been done by Dr. Langrehr on the following day. The uterus, ovaries, and tubes had been found healthy. The omentum was, in places, densely adherent. The abscess was situated

within the broad ligament, and had extended upward behind and two inches above the ramus of the pubes. It had contained about six ounces of thick pus, which had been evacuated by an incision in the left inguinal region, directly above Poupart's ligament. The ultimate recovery had been perfect.\*

Case V.+-Mrs. G., aged thirty years, secundipara, had been delivered on January 18, 1893, of a living child, after a normal labor. The placenta had been delivered by the introduction of the hand. The following day Mrs. G. had had a temperature of 104° F., and had been suffering much from pain in the right groin and from tympany. On the night of the 20th the speaker had seen her in consultation. The temperature was 103° F., the pulse 110, and there was marked tympany and much tenderness in the right groin. A striking feature in the case had been that, although the bowels had been very much distended, the abdominal wall itself had not been very tense. The coils of distended bowels could be very plainly observed through the abdominal wall. The bowels had not been moved for four or five days. The patient had been put upon quinine, strychnine, and digitalis, and the bowels had then been freely moved. Vaginal and intra-uterine douches of corrosive sublimate had been employed, although the lochial flow had not been foulsmelling. The patient's condition had remained very much the same until the seventh day, when the right broad ligament had become infiltrated, so much so as to be plainly palpable above the brim of the pelvis in the right groin, while, from below, the anterior and right quarter of the pelvis had been filled with exudate closely attached to the pelvic wall and displacing the cervix backward into the hollow of the sacrum. This exudate had begun to disappear about the fourteenth day, and had been absorbed very rapidly. Convalescence had been further interrupted by a nephritis, possibly of septic origin, and also by severe intestinal pain accompanied by diarrhoa, presumably due to inflammation of the large bowel. This patient had been seen in consultation by Dr. Goodell and Dr. Parish. She had eventually made a good recovery.

CASE VI.—Mrs. H., aged twenty-eight years, a secundipara, had been delivered of her second child in March, 1891, the labor having been conducted by a midwife. She had been infected and had been extremely ill. He saw her, in consultation with Dr. Leopold, five weeks after the labor. At that time she was prostrated, with a rapid pulse, "leaky" skin, chills, irregular temperature—in fact, the classical symptoms of septic intoxication.

On examination the right broad ligament had been found indurated, and also a mass of exudate extending on the right side of the abdomen almost as high as the umbilicus. From the extent of the mass it had been supposed that a right pyosalpinx with an intraperitoneal abscess had existed; but, in view of the puerperal history and the existence of a cervical laceration, the possibility of a true pelvic abscess had been discussed. A median abdominal incision had been made on April 16th, and the abdominal viscera in the lower right quarter of the pelvis had been found fused by adhesions. The patient had taken ether so badly, having become cyanosed while still partly conscious, and the pulse had been so weak, that Dr. Noble and the gentlemen present had been convinced that to attempt the separation of the adhesions, and the evacuation of the pus from above, would result in her death on the table from ether. An unsuccessful attempt had been made to reach the pus by an incision made near the anterior superior spine of the ilium without giving more ether. The exploration had not been pushed,

<sup>\*</sup>The first four cases were reported in the Medical News for August 29, 1891.

<sup>+</sup> Annals of Gynacology and Padiatry, June, 1893.

owing to the patient's bad condition. The patient had then been put to bed and had improved for some days. The operation had again been proposed and chloroform had been selected as the amesthetic, which had produced as much cyanosis as the ether had done. An incision had been made directly over the broad ligament, the uterus had been located, and the index finger had been forced into the broad ligament, evacuating several ounces of pus. With rubber drainage a satisfactory convalescence had followed.

On October 27, 1892, Dr. Noble had operated on Mrs. H. to cure a ventral hernia which had formed at the site of the third incision. On opening the abdomen he had been surprised to find that the adhesions throughout the right side of the abdomen, which had been universal eighteen months before, had disappeared, except a point of adhesion between the omentum and hernial sac, and another between the omentum and broad ligament. Both appendages were perfectly healthy. This fact demonstrated what was believed when the pus had been evacuated—namely, that it had not been a pyosalpinx, but an abscess of the broad ligament.

The disappearance of the very extensive adhesions in this case was worthy of record as showing that peritoneal adhesions were not necessarily permanent.

It was of interest to report that, during the summer of 1898, this patient had been delivered of a living child after a normal labor, and that she was at present in good health.\*

CASE VII.—Mrs. F., aged eighteen years, had been confined on May 8, 1893. She had had a mild puerperal sepsis and had been in bed for two weeks. The following month she had been constantly sick, having been in and out of bed, suffering with pelvic pain, anorexia, and having had more or less fever. (The temperature and pulse he did not know, as he had not been in attendance.) She had come under his care six weeks after her confinement, and had been admitted to the Kensington Hospital for Women. Examination had shown a large inflammatory mass in the pelvis, absolutely anchored to the left pelvic wall. She had been under observation for two weeks, with the temperature fluctuating between 99° and 102° F., and with the general evidences of mild septic absorption, such as anorexia, sweats, chilly sensations, and increased pulse-rate.

Believing that pus was present in the pelvis, either in the form of a true pelvic abscess or a pyosalpinx, an abdominal section had been made on June 26, 1893. The following conditions had been found: The uterus was fairly well involuted and was displaced upward and backward by a mass in the left broad ligament. The right broad ligament and the right Falloppian tube and ovary were entirely normal, as had been demonstrated not only by touch, but by delivering the ovary and tube through the abdominal incision. The omentum was adherent to the anterior face and upper border of the left broad ligament in front of the Falloppian tube. This adhesion had been separated. The left ovary and tube had been found to be entirely normal, the meso-salpinx being normal, soft, and movable. This had been demonstrated not only by touch but by vision, the woman being in the Trendelenburg posture, so that the entire left side of the pelvis had been in plain view. The left broad ligament had been very much infiltrated with inflammatory material and firmly anchored to the anterior and left bony wall of the pelvis. Fluctuation had not been apparent. It had been determined to close the abdomen, and, if septic symptoms persisted, to open the broad ligament from below. That portion of the omentum which was adherent to the broad ligament had been ligated and cut off. A small gauze drain had been placed against the broad ligament where the omentum had been separated, so that, should pus make its appearance at this point, it would find its way out through the abdominal incision.

The patient's convalescence had been uninterrupted; the temperature had rapidly dropped to the normal, and her general condition had steadily improved. The gauze drain had been removed, good union of the abdominal incision had been obtained, and the patient had been discharged from the hospital at the end of four weeks. In the meantime not only had her general condition very much improved, but the pelvic mass had almost disappeared.

This patient had consulted Dr. Noble on January 9, 1894, to ascertain the cause of a suppression of menstruation of three months. He had found her to be between three and four months pregnant. A careful examination of the left broad ligament had failed to discover any evidence of the former cellulitis, the left broad ligament feeling exactly like the right one.

The evidence of the existence of acute puerperal cellulitis as a primary condition in this case was absolute. There had not been even a complicating pelvic peritonitis in the ordinary sense of that term, merely a point of adhesion between the omentum and the broad ligament, which had been, of course, due to a small circumscribed area of peritonitis. He had been able to demonstrate these conditions to a number of physicians who were present, including among others Dr. Fullerton, of the Woman's Hospital.

What he wished especially to insist upon was that in this case neither Falloppian tube had been involved in the inflammatory process, that both had been entirely normal. The left Falloppian tube and its mesentery had scarcely been even congested. The circumscribed area of peritonitis where the omentum had been adherent to the broad ligament had been plainly due to the fact that the inflammation had extended directly through the broad ligament to the peritoneum, leading to the adhesion of the omentum. That this was possible had been denied by those who maintain that all pelvic inflammation was due to the infection which had spread through the Falloppian tubes. In this case the conditions presented had been unmistakable.

There thus had been seven cases, in all of which, except the third and fifth, an abdominal section had been made, so that we had the evidence not only of the usual physical examination, but also that obtained from an intraperitoneal examination. In Cases I, II, IV, and VII, the abdomen had been opened and the uterine appendages examined, and it had been demonstrated that they had been either free from disease, or, at the most, lightly attached by recent adhesions. In these four cases there was not a shadow of a doubt that the disease had been in the broad ligament, and that it had spread to the broad ligament directly from the uterus or the vagina by way of the lymphatics.

Case VI had been undoubtedly not a case of pyosalpinx, and he had no question himself that the pus had been located in the broad ligament. A carping critic might affirm that, even although it had not been a pus tube, the pus had been intra-and not extra-peritoneal, and that it had been due to suppurative peritonitis. His opinion that the pus had been in the broad ligament was based upon the fact that the pelvic exudate had been anchored to the anterior and right pelvic walls, and that when he had cut down upon the mass he had recognized the uterus and had torn through the broad ligament with his finger in front of the Falloppian tube.

The evidence in Cases III and V was not so absolute as in the others, and they were included in this list not for the sake of demonstrating the occurrence of puerperal cellulitis, as was done by the other cases, but because of their relative bearing upon the subject.

The foregoing cases demonstrated several interesting facts with reference to obstetrics and gynæcology:

- That in the puerperal state, pelvic cellulitis and true pelvic abscess occurred as the result of septic inflammation.
- That inflammation might spread from the vagina or uterus along the pelvic lymphatics to the broad ligaments without involving the Falloppian tubes.
- That peritonitis could be set up by the spread of inflammation from the broad ligaments to the peritonæum without involvement of the Falloppian tubes.
- That very extensive pelvic exudate and intraperitoneal adhesions could be absorbed.

It hardly seemed worth while to bring evidence to bear in support of the first proposition, and it would not be called for had it not been that a few men of wide experience maintained the contrary. Having been able to present absolute evidence in the shape of carefully and thoroughly observed cases occurring in his own practice, he would not take the time or trouble to make reference to the literature.

What he had said concerning proposition one was equally true of proposition two, which was distinctly proved by certain of the foregoing cases. Case VII was a beautiful illustration of the fact that a very extensive puerperal cellulitis could be present and yet the Falloppian tubes be entirely healthy. In this case they had scarcely been, if at all, congested, and the mesosalpinx had been entirely free from infiltration.

The third proposition was likewise proved, especially by Cases IV and VII. In both of these cases the omentum had been adherent to the broad ligament, although the tubes had been free from disease. He had no doubt that pelvic peritonitis was usually due to the spread of inflammation from the endometrium through the Falloppian tubes to the peritonæum, but these cases showed that this rule was not without excep-Numerous other exceptions had come under his observa-For instance, a short time ago he had done a hysterectomy for a fibroid tumor, in which the tumor, being impacted in the pelvis, had been adherent to the rectum and posterior pelvic wall, over an area of at least nine square inches, and yet in that case the Falloppian tubes had been entirely normal. In several cases of appendicitis he had found the peritonitis to extend to the pelvis, the Falloppian tubes having nothing to do with its occurrence. Moreover, it was a well-known fact that when small tumors, especially dermoids, had become wedged in the pelvis or twisted upon their pedicles, peritonitis had ensued. Likewise, that in cases of malignant disease of the abdominal or pelvic organs adhesions were almost always present. Therefore it must be admitted that pelvic peritonitis could occur independent of salpingitis.

Case VI demonstrated the fourth proposition. In that case the entire right lower quarter of the abdomen had been fused together by recent peritoneal exudate, and light adhesions had formed in the left half of the pelvis, yet eighteen months later, when the abdomen had been reopened, the entire mass of adhesions had been absorbed, with the exception of a small point between the omentum and right broad ligament, and another small point between the omentum and the hernial sac. Owing to the very extensive character of the adhesions in this case, it was a striking example of the fact that recent adhesions could be entirely absorbed.

Two women of the seven whose cases have been detailed in this report have been delivered of living children since their recovery from the attack of acute puerperal pelvic cellulitis.\*

The subsequent history of four of the other five women was unknown to him. The fact that two of these women had borne children was of interest because of its bearing upon the question of the relation of pelvic exudates to sterility. As this paper had dealt only with demonstrated facts, the speaker merely suggested that the occurrence of pregnancy after the existence of extensive exudates, forming during the puerperal state, was best explained in many cases by the fact that the condition presented was a puerperal cellulitis rather than a diseased tube. It was a severe tax upon his credulity to accept the statement that extensively diseased tubes, more especially pus tubes, could so far recover as to permit the occurrence of pregnancy; and he believed that the true explanation in not a few cases of pregnancy following the recovery from puerperal pelvic inflammation was that the disease had originally been in the broad ligament and not in the Falloppian tube.

He wished to say a few words concerning the relative frequency of acute puerperal cellulitis and inflammation of the Falloppian tubes. He believed as firmly as any one that pelvic cellulitis and true pelvic abscess were comparatively rare conditions, and that the usual variety of pelvic inflammation was a salpingo-peritonitis. He had not met with pelvic cellulitis except in the puerperal state, and had no reason to believe that it occurred in the non-puerperal state, except as a result of infected wounds of the vagina and perinæum. As such conditions were very infrequent, a pelvic cellulitis in the non-puerperal state would be a surgical curiosity.

He had added these remarks lest it might be inferred by the unthinking that he was desirous of supporting the old and abandoned theory of Nonat and Emmet concerning pelvic inflammation. At the same time he was glad to be able to present incontestable proofs of the occasional occurrence of acute puerperal pelvic cellulitis and true pelvic abscess.

Dr. Daniel Longaker said that it was a question in his mind whether septic puerperal troubles so frequently resulted in chronic salpingeal disease as did some other conditions. He believed that gonorrheal disease was more frequently the cause of pyosalpinx than was puerperal sepsis. He had seen several instances where abdominal section had been done at varying intervals, from a few months to several years, after the occurrence of severe metro-peritonitis, and the amount of tubal trouble had been very slight.

In regard to the true nature of these masses which we occasionally found in septic infection of the puerperal period, he believed that a proportion, and probably a large proportion, were due to cellulitis. He had seen a number of such cases where the masses had disappeared and the women had become perfeetly well and had borne other children. This was hardly compatible with the supposition that these had been cases of pyosalpinx, which he looked upon as an incurable condition and as inducing sterility. In his experience true pelvic abscess had been more frequent than we had been led to believe by the statements of some. In one case the abscess had discharged through the bladder, and the woman bad made an imperfect recovery; pyuria had continued a long time, and death had finally occurred from hæmatemesis. Another termination was by spontaneous discharge in the region of the groin, and of this he had seen two illustrations.

A noteworthy point in considering the atiology was that in many of these cases the labor was an easy one and of brief duration. In such cases he thought that it was safe to assume a slight laceration of the perinæum, and infection at that point and extension along the lymph paths. There was another point in his case (the first in Dr. Noble's paper), the full value of which had not occurred to him at the time. The surroundings of the patient had not been ideal. The first thing noticed on

<sup>\*</sup>Since writing this article Dr. Noble has learned that Dr. Himmelwright's patient (Case III) has been delivered of a living child after a normal labor.

entering the house had been the odor from an old water-closet. The woman had lived here in this tainted atmosphere continuously during the latter part of her pregnancy, and everything that had come in contact with her body had been exposed to this infection; her powers of resistance had thus been lowered, and it was probable that infection had occurred in that way, and not through any fault of the doctor in attendance. The force of this observation was evident when we recalled the fact that in rural districts septic infection during the puerperal period was comparatively infrequent. On this same street he had attended a woman living in a house through the cellar of which passed a terra-cotta drain through which passed the drainage of several houses. A short time before labor the drain had become obstructed, and had been opened and left open. This woman had had a short labor with forceps, and within fortyeight hours a most violent septic infection had developed. In a short time the patient had become maniacal, and died within a week.

Dr. George E. Shoemaker said that this discussion had always seemed to him like that of the two knights viewing different sides of the same shield. It was reasonable to suppose that abseess might occur in any part of the body in conditions of profound toxemia. He had opened an abscess in the lower lip in puerperal septicæmia. Abscess would form at any point of lowered vitality. This might occur in the broad ligament where there had been traumatism. It was easy in these cases to explain the direct channel of infection.

Dr. George I. McKelway said he had seen two cases such as Dr. Noble had described. One had been under the care of Dr. Hirst at the Philadelphia Hospital. The woman, after childbirth, had had a large hard mass to the left of the uterus. After several days of high temperature, etc., Dr. Hirst had determined to operate, but, on coming prepared to do so, had found the temperature down and the woman's whole condition greatly improved, and he had concluded to wait. The woman's condition remained good, and in two or three weeks the hard mass had gradually disappeared. After-examination had shown the tubes and ovaries perfectly free. The second case had been under his care last summer, in the Presbyterian Hospital. A woman had been sent in with a stinking placenta which had been retained three days. He had removed it with his fingers, had irrigated, and packed. Some days later an exudate on the left side had developed. From her previous and present condition, and the temperature, etc., he had been sure that there had been an abscess. On opening the abdomen, ten days after admission, he had found the left broad ligament and left side of the pelvis occupied with a great mass of hard exudate. Dr. J. Hendrie Lloyd, Dr. William C. Lott, and several resident physicians had been present. To them he had demonstrated that this condition had been in the broad ligament and the pelvic tissue, and not in either tube or ovary of either side, by bringing the tubes and ovaries of both sides into view at the same time, and showing them to be perfectly normal and healthy. As the exudate had been almost as hard as a paving stone, pus not having formed, he had closed the wound and had awaited developments. The mass had disappeared in about three weeks, and the woman had made a perfect recovery.

Dr. Langrehr said he was fully in accord with what Dr. Noble had said with regard to the possibility of pelvic cellulitis occurring without having a direct source from a diseased Falloppian tube. One of the cases reported had been one on which he had had the opportunity to operate. The patient had been a young married woman, aged sixteen years. He had operated for laceration of the perinæum, and infection had followed. On opening the abdomen, he had ascertained that the ovaries and tubes, as well as the womb, had been free from ad-

hesions. He had found the abscess in the left inguinal region and had opened it above Poupart's ligament and drained it thoroughly. The patient had recovered.

Dr. Henry Leaman said he had had a dozen cases confirmatory of Dr. Noble's position. One case had discharged through the bladder and another through the bowel. In one case, where the afterbirth had been removed in pieces by a midwife, a distinct tumor had formed, which afterward had disappeared. The woman was now pregnant. He believed, also, that distended tubes might heal under proper treatment. This was not after puerperal trouble, but after syphilitic infection. There was no reason why a syphilitic enlargement should not be cured.

Dr. Noble said that the conclusion which he had drawn from these facts was that the position with reference to exudates which had formed after the puerperal state should be different than it was where such exudates were found in the non-puerperal condition. As it was a fact that many of these exudates were in the broad ligament and got well if let alone, he thought that pelvic exudates following labor should be treated without operation, unless the indications of pus were very marked and there was danger of the woman dying from the absorption of pus. A goodly number of such women would get well and retain their fertility.

Exhibition of a Case of Acromegaly, with Remarks on the Treatment by Desiccated Thyreoid Gland.—Dr. Soldman Solis-Cohen presented this case to the society in order to exhibit some structural changes not found, or at least not recorded, in every case of acromegaly, and to call attention to the apparently good results of treatment with desiccated thyreoid gland.

As full details of the case would be published in the *International Clinics* (in his report of a lecture delivered some time ago to his polyclinic class), he would be brief in the present instance.

The patient, who was fifty-two or fifty-three years of age, had applied to the Philadelphia Polyclinic about eighteen months before for relief from an excruciating headache, which had for many months been so intense at times as to prevent his lying down, pressure on the scalp increasing the pain. Attention had at once been attracted to the peculiarities of the facial structures presented, and further examination had demonstrated the characteristic curvature of the back and enlargement of the hands and feet. Photographs of the patient, taken twenty years before and six years before respectively, bore out his statement that his features had materially altered within the last four years, although the later photograph showed the beginning of the change.

He had had to enlarge his hat-band twice and his shoes twice within three years. The shoes were a little longer but much broader than formerly. The hands were broadened rather than lengthened; the fingers not exactly "sausage-shaped," but thick and clumsy. Distortion of the joints was to be attributed to his occupation, and probably antedated the development of the acromegalic conditions. Part of the coarseness of the skin of the hands might likewise have been due to occupation. His hands to-day, however, were smaller than when he had first come under treatment, as shown by the tracings and measurements, and also by his statement that a pair of gloves bought some years before, which had been too small for him last year, could now be worn.

The enlargement and projection of the superciliary ridges, the lateral projection of the malar bones, the broadening and deepening of the chin, gave the face the characteristic length-ened elliptical outline. The great enlargement of the nose, the thickening and projection of the lips, the heavy folds, the deep furrows, and the somewhat greasy texture of the skin, espe-

.

cially of the forehead, the stiffening and projection of the auricular cartilages, completed the picture. The lower jaw did not, however, project beyond the upper jaw. The teeth were bad. The tongue was thickened and deeply fissured. The voice was deep and had a monotonous quality, the latter only partly attributable to his "boilermaker's deafness." The laryngeal and tracheal cartilages were almost if not completely ossified. The thyreoid gland could not be demonstrated. The forward thrust of head and neck from curvature of the cervicodorsal spine threw the clavicles well out from the windpipe. leaving a great hollow just above the sternum. The clavicles were enlarged, the scapulæ were enlarged, the ribs were broadened and apparently in contact, and the costal cartilages seemed to be ossified. In consequence, although the narrowing of the chest-an apparent lateral compression-and the percussion phenomena showed absence of emphysema, it would be observed that his breathing was scarcely at all thoracic. was an almost inappreciable rise and fall of the clavicles, showing slight vertical motion of the thorax as a whole, and, on great inspiratory and expiratory exertion, an expansion of a half to a centimetre could be determined at the nipple line. Breathing was almost exclusively abdominal. This showed, as did his previous case, and some cases of Dr. Dercum's and others, that the disease involved the bones of the thorax as well as those of the extremities.

The patient was becoming feeble; his muscles were wasting, though as yet electric examination showed only quantitative change.

He had vaso-motor phenomena—flushing, occasional vertigo, and polyuria. The urine had been deficient in solids, but had not contained sugar or albumin. We had not, indeed, demonstrated anything abnormal in it. This he attributed, however, to defective methods of examination. He had no doubt that careful chemical analyses would show in the urine the results of altered metabolism. Since treatment with thyreoid powder had been instituted the quantity of urinary water had decreased and the urea content had risen. Ordinarily the thyreoid preparation increased both water and solids. Superficially the diminution of polyuria by a diuretic would seem to be an illustration of the so-called "homeopathic law." A moment's reflection, however, showed the action to be simply a correction of disordered metabolism, through which the production of toxins giving rise to polyuria was diminished. Another result of the administration of the thyreoid powder had been to completely relieve the distressing headache.

At one time, after a long absence from the clinic, the patient had returned complaining of violent soiatic pain. It had failed to yield to ordinary measures, but had disappeared after recourse to thyreoid nedication. Five grains of the preparation of desiccated sheep's thyreoid exhibited by Dr. Solis-Cohen to the society last year had been given in capsule every morning.

Upon the somnolence, however, no effect had been obtained. The patient could still go to sleep upon the slightest provocation—indeed, without any. He had fallen asleep while waiting his turn at the dispensary, and had frequently missed appointments through sleeping in his chair over the time set. He said that he could keep awake, however, while at work; but as he could no longer do the hard work to which he had been accustomed, he had not for some time had steady employment.

Dr. Jackson had examined his eyes, and had found no lesion of the fundus and no error in the visual field. This went to confirm the view that hemiopia and other visual errors were merely secondary phenomena, due to pituitary enlargement, and that the latter was not necessarily a feature of the pathologic complexus. The speaker was inclined to believe that early treatment with thyreoid preparations would entirely prevent

overgrowth of the pituitary body, embryologic analogy seeming to indicate that it was an attempt at compensatory hypertrophy, ill-directed and baneful only by reason of the altered position of the structure.

## Book Notices.

The Care and Feeding of Children. A Catechism for the Use of Mothers and Children's Nurses. By L. EMMETT HOLT, M. D., Professor of Diseases of Children in the New York Polyclinic, etc. New York: D. Appleton & Company, 1894. Pp. 8-9 to 66. [Price, 50 cents.]

The author states in his preface that when the practical training school for nursery maids was established in this city in 1889, the need was felt for some simple manual to put into the nurses' hands. He accordingly wrote out a series of questions and answers formulating those things that were matters of daily observation and practical hospital work. This book contains these questions and answers, and is published for the purpose of assisting mothers and nurses.

He has arranged his subject under three sections: The care of children, infant feeding, and miscellaneous.

The text is clear and simple and may be understood by any reader moderately conversant with the English language. The advice given is excellent, and covers the various subjects about which the family physician is so often questioned. The volume should be in the hands of all young mothers and of every nursery maid; and physicians may feel assured that they may recommend the book as a vade mecum from which their patients may acquire the information, usually so much sought for, regarding the best methods of caring for young infants.

Diseases of the Skin. An Outline of the Principles and Practice of Dermatology. By Malocia Morris, Surgeon to the Skin Department, St. Mary's Hospital, London, etc. With Eight Chromo-lithographs and Seventeen Woodcuts. Philadelphia: Lea Brothers & Company, 1894. Pp. xii-556. [Price, \$3.50.]

It has been the author's aim to present in this volume the clinical facts and the principles of treatment of skin diseases, based on the results of modern research, in an essentially clinical and practical manner.

In the first chapter, on the pathology of the skin, Metschnikoff's theory of inflammation is briefly described, and the relation of protozoa and bacteria to skin diseases is mentioned, with reference to the latest data.

In the chapter on classification the author refers to the several more important schemes of classification, and, while he propounds no formal scheme of classification, he follows the lines suggested by Unna.

The chapter on the principles of diagnosis is excellent; its practical features can not but be most useful to all that master it.

The author then considers the skin diseases under the headings of affections of the skin dependent on nerve disorder, artificial cruptions, eczema, pityriasis, psoriasis, local inoculable diseases, general inoculable diseases, diseases of the skin glands, benign and malignant neoplasms, and malformations.

The colored plates and illustrations are very good. The text is well printed, the volume is easily handled, and we believe it is destined to have an extensive and deserved popularity. A Manual of Instruction in the Principles of Prompt Aid to the Injured. Including a Chapter on Hygiene and the Drill Regulations for the Hospital Corps, U. S. A. Designed for Military and Civil Use. By Alvah H. Dorry, M. D., Major and Surgeon, Ninth Regiment, N. G. S. N. Y., etc. Second Edition, revised and enlarged. New York: D. Appleton & Company, 1894. Pp. xvi-304. [Price, \$1.50.]

THE author has made such additions to this new edition of his excellent manual that it contains eighty pages more of text and several new illustrations.

In the chapter on antiseptics, disinfectants, and deodorants the author has incorporated the practical instructions for disinfection and fumigation published by the New York City Health Department, but why he has included instructions for the sterilization of milk for feeding infants is not apparent.

In the chapter on contusions and wounds the author disposes of his subject in a practical manner, avoiding the temptation to expatiate on the effects of missiles fired at various ranges, especially those of the latest improved projectiles.

A short but useful chapter on hygiene has been added. The final chapter on the transportation of the wounded has been elaborated by the addition of the drill regulations for the United States army.

This edition will sustain the reputation acquired by its predecessor, and the work is likely to have a wide field of usefulness.

#### BOOKS, ETC., RECEIVED.

Materia Medica, Pharmacology, and Therapeutics. Inorganic Substances. By Charles D. F. Phillips, M. D., LL. D., F. R. S. (Edin.), Late Lecturer on Materia Medica and Therapeutics at the Westminster Hospital Medical School, etc. Second Edition. London: J. & A. Churchill, 1894. Pp. xiv-898. [Frice, 21 shillings.]

The Care and Feeding of Children. A Catechism for the Use of Mothers and Children's Nurses. By L. Emmett Holt, M. D., Professor of Diseases of Children in the New York Polyclinic, etc. New York: D. Appleton & Company, 1894. Pp. 8-9 to 66. [Price, 50 cents.]

A Manual of Instruction in the Principles of Prompt Aid to the Injured. Including a Chapter on Hygiene and the Drill Regulations for the Hospital Corps, U. S. A. Designed for Military and Civil Use. By Alvah H. Doty, M. D., Major and Surgeon, Ninth Regiment, N. G. S. N. Y., etc. Second Edition, revised and enlarged. New York: D. Appleton & Company, 1894. Pp. xvi-304. [Price, \$1.50.]

Diseases of the Skin. An Outline of the Principles and Practice of Dermatology. By Malcolm Morris. Surgeon to the Skin Department, St. Mary's Hospital, London, etc. With Eight Chromo-lithographs and Seventeen Woodcuts. Philadelphia: Lea Brothers & Company, 1894. Pp. xii-556. [Price, \$3.50.]

Further Remarks on the Occurrence of a Form of Nonalbuminous Nephritis other than Typical Fibroid Kidney. By D. D. Stewart, M. D. [Reprinted from the Medical News.]

A System of Legal Medicine. By Allan McLane Hamilton, M. D., Consulting Physician to the Insane Asylums of New York City, etc., and Lawrence Godkin, Esq., of the New York Bar. Illustrated. Volume I. New York: E. B. Treat, 1894. Pp. 8 to 657. [Price, \$5.50.]

An International System of Electro-therapeutics for Students, General Practitioners, and Specialists. By Horatio R. Bigelow, M. D., Permanent Member of the American Medical Association, etc., and Thirty-eight Associate Editors. Thoroughly illustrated. Philadelphia: The F. A. Davis Co., 1894. Pp. xxxii-1160. [Price, \$6.]

A Clinical Manual. A Guide to the Practical Examination of the Excretions, Secretions, and the Blood, for the Use of Physicians and Students. By Andrew MacFarlane, A. B., M. D., Instructor in Neurology and Diseases of the Chest in the Albany Medical College, etc. New York and London: G. P. Putnam's Sons, 1894. Pp. xii-138.

Traité pratique de gynécologie. Par le Dr. A. Auvard, Accoucheur des hôpitaux de Paris. Deuxième édition, revue et augmentée. Avec 655 figures dans le texte et 12 planches en couleur hors texte. Paris: Octave Doin, 1894. Pp. 870. [Prix, 18 fr.]

Études de chirurgie infantile. Les hernies inguinales de l'enfance. Par le Dr. G. Félizet, Chirurgien de l'Hôpital Tenon. Avec 73 figures dans le texte. Paris: G. Masson, 1894. Pp. xiv-42. [Prix, 10 fr.]

Analyses of Twelve Thousand Prescriptions. Being Statistics of the Frequency of Use therein of Official and Unofficial Preparations. Compiled by W. Martindale, F. C. S. London: H. K. Lewis, 1894. [Price, 2s. 6d.]

## Miscellany.

The Causes and Treatment of Infantile Diarrhoea.—The Journal de clinique et de thérapeutique infantiles for May 24th publishes a paper on this subject by Dr. G. Variot in which he says that the majority of infants who are attacked with diarrhoea and vomiting are those artificially fed or those who are given solid food at a time when their digestive organs have not attained their full activity and power. Where there is hereditary syphilis or scrofulo-tuberculosis, the children are more susceptible to digestive troubles, as these affections greatly impair the young organism, the digestive organs of which are in a constantly changing condition. In these cases diarrhoea is only an epiphenomenon, and it is not astonishing if it resists the usual means for combating it, for it may be combined with tuberculous lesions of the intestine or of the mesenteric ganglia.

Children nursed exclusively at the breast are rarely attacked with persistent diarrhea, although, even in this case, too frequent nursing will cause a gastro-intestinal dyspepsia, accompanied by repeated vomiting and diarrhea. A constant change also of wet nurses is, again, a cause of this affection in infants.

With regard to solid food, physicians have insisted that milk is the only diet for infants, but it seems almost impossible, says Dr. Variot, to impress this simple fact particularly upon the common people, who, in France, and in America, according to Dr. L. Emmett Holt, obstinately cling to the idea that the sooner the children are fed on solid food the quicker they will grow. It is generally admitted that starchy food should not be given to infants before dentition occurs. At this age the salivary and intestinal glands are powerless to saccharize the starchy substances, which irritate the mucous membranes and undergo injurious fermentations. In some cases which had come under the author's observation, where solid food had been given to the children, the abdomen was distended and dilated, and at the linea alba there was a true eventration, so that one or two fingers could be introduced between the two recti muscles, and this eventration indicated that the abdominal wall had been in some way forced open by the flatulent distention of the intestines. This flatulence was without doubt connected with the abnormal gaseous fermentation of the starchy substances.

Another cause of diarrhea in infants is the quality of the milk, which is often inferior, and the milk which is sold to the poor, especially in large cities, is often dirty and adulterated. Much sickness and many deaths also are attributed to the use of the nursing bottles with long rubber tubes, which are so difficult to clean properly, and to the rapid alterations of the milk, into which the breath of the child is constantly passing; the milk also is often diluted with impure water and contains septic germs which provoke very dangerous fermentation. The

statistics of deaths from diarrhœa, drawn up by different observers, all go to show that the mortality is greater in June, July, and August, and at this time the digestive organs should be carefully watched, particular attention being paid to the quality of the milk and to its sterilization; if necessary, the quantity should be somewhat reduced at each meal. Some writers have observed epidemics of diarrhœa, and some cases of contagion. Although not much importance is attached to the latter, it is well, the author says, to take children to the country during the hot weather. Another cause of diarrhea is dentition, the effects of which should not be neglected. The author does not share the popular idea that diarrhœa from this cause is salutary and needs no attention; at this time the digestive organs of infants should be carefully watched. As soon as the diarrhea appears the child should not nurse oftener than every three hours; if it is artificially fed, the milk should be diluted with a third of limewater. Before the child nurses a teaspoonful of the following mixture should be given: Distilled water, two ounces; lactic acid, half a drachm; tannin dissolved in alcohol, eight grains; and syrup of quince, five drachms.

For a child fed artificially, the author always prescribes sterilized milk, and gives careful directions for the antiseptic cleansing of the bottle. The best proof, he says, that diarrhœa, if it is treated from the first day of its appearance, is due to the bad quality of the milk, is that it yields to treatment in two or three days after the administration of sterilized milk. In some of the author's cases this was the only agent used to effect a recovery from attacks of diarrhœa due to bad milk, toastwater, etc. If sterilized milk is properly prepared and of good quality, it is the best food for children artificially fed, as the sterilization destroys all morbid or noxious germs, and the author has observed that, as a rule, it is well borne by infants.

The Nucleins and Nuclein Therapy.—In an address delivered before the Illinois State Medical Society by Dr. Victor C. Vaughan, of Ann Arbor, a report of which is published in the Journal of the American Medical Association, he says that recent investigations have indicated that a knowledge of the nucleins would probably be of service to practitioners, also that some of them promise to be of therapeutical value. Miescher, he says, was the first to study the nucleins with a fair appreciation of their importance, and it was he who named them. The corpuscles from pus were obtained by the addition of a dilute solution of sodium sulphate, subsidence, and decantation. Then they were digested with pepsin and hydrochloric acid so long as peptones were formed; this left the nuclei of the cells. These were found to be rich in phosphorus and soluble in dilute alkalies. From the alkaline solution the substance is precipitated by dilute acids. The lability of the nuclein molecule and its power of recuperation after partial decomposition have been demonstrated by Miescher, and it has been shown that certain organic and inorganic bases may be placed within or drawn from the nuclein molecule without any visible modification of the character of the substance. Hoppe-Seyler has prepared nucleins from yeast; Lubavin, from casein; Plosz, from the nuclei of the blood-corpuscles of birds; and Miescher, from the volks of eggs.

Dr. Vaughan and others have experimented with nuclein obtained from yeast, eggs, the spleen, the thyreoid gland, and the testes, and all of them have been found to be distinctly bactericidal. They have also demonstrated that the germicidal constituent of blood serum is a nuclein which is undoubtedly furnished by the multinuclear white corpuscles. When it had been shown that the nucleins were germicidal, it remained to be seen whether or not they might be used to prevent or arrest

the growth of germs in the animal body. The author gives a long and comprehensive account of his experiments with rabbits and guinea-pigs in which he used a solution containing about two per cent. of yeast nuclein, and from the results obtained he draws the following conclusions: 1. Rabbits and guinea-pigs may be protected against virulent cultures of the diplococcus of pneumonia by previous treatment with hypodermic injections of a solution of yeast nuclein. 2. The immunity thus secured is not directly due to the action of the nuclein as a germicide. 3. The process of this immunity is an educational one, and depends upon the stimulating effect of the nuclein upon an organ whose function it is to protect the body against bacterial invasion. 4. The longer the use of the nucleins is continued and the more frequently they are administered, the more complete is the immunity obtained. 5. In order to obtain this immunity, inoculation with the germ must follow soon after the last treatment with the nuclein. Dr. Vaughan has also made some attempts to produce immunity from tuberculosis in guinea-pigs, but so far the results have not been altogether satisfactory, and in some cases they have been contradictory. He believes the nucleins to be entirely free from poisonous properties. He has injected subcutaneously in a man an ounce and a half of a two-per-cent. solution of yeast nuclein at a time without any effect except the temporary irritation produced by so much fluid being injected, and he has also given from six to eight ounces of the same solution by the mouth during twenty-four hours without any bad effect. In some persons, however, a much smaller dose might cause a marked elevation of temperature. For instance, in one patient, a large and apparently robust man who was suffering from muscular rheumatism, and in whom tuberculosis of the neck of the bladder had recently been detected, a hypodermic injection of forty drops of the two-per-cent. solution of yeast nuclein caused the temperature to rise from two to four degrees. In a few cases the injection of eighty drops or more has been followed by a chill and an elevation of the temperature, and a redness like that of erysipelas has appeared and lasted for about twentyfour hours.

In tuberculous patients the effect of repeated injections has been a lowering of the temperature. Dr. Vaughan has used daily injections of the nuclein for six months or more without observing any injurious effects from their continuous use. In twelve cases of membranous amygdalitis he employed the nucleins alone with good results, the fever disappearing within twenty-four or forty-eight hours at the most. In four cases of streptococcus diphtheria good results were also obtained from their employment. Still another case where it was used successfully was that of a man who had been under treatment for an indolent ulcer of the leg. After other measures had been tried, the nuclein was used alone, and eighty minims of a twoper-cent, solution of yeast nuclein were injected into the tissues around the ulcer. Eight injections were made and the ulcer healed perfectly. Two months have passed since the last treatment, and there has been no return of the trouble.

The action of the nucleins in giving immunity from pneumonia germs is not due to its direct germicidal effect, and the author says that we must look for curative agents in one or the other of the following classes: 1. Non-poisonous germicides of cellular origin. 2. Substances which stimulate the activity of the organs whose function it is to protect the body against these diseases. While there are in the nucleins substances of the first class, he believes that the nucleins belong also to the second class. The phagocytic theory, he says, teaches that the multinuclear white corpuscles are the natural defenders against bacterial invasion, and if the nucleins are to prove of any value in the treatment of tuberculosis, it will probably be due to the

fact that they increase the multinuclear white corpuscles. However, the author thinks that it is only in recent cases that any benefit may be expected, and even in regard to these there must be more abundant material and a longer experience in order to speak with any certainty.

Opium with Calcium Chloride as a Hæmostatic.-The Indian Medical Record for May 1st publishes an article on this subject by Dr. William Huntly, of Kotah, who has used and tested the value of this combination in different kinds of hæmorrhage. He cites the following cases as being the most important examples of the various uses to which it may be put: A man came to him on the morning following the extraction of a lower molar tooth. The bleeding had been very severe, and blood still flowed from the gum. The author stuffed the cavity with lint soaked in liquor ferri perchloridi, but this did not stop the bleeding. The man was very weak. Remembering the effect of opium, he gave him a full dose of the tincture, and in less than a minute the pupil contracted and the bleeding stopped. The patient was then ordered to take twenty grains of calcium chloride in an ounce of rain-water every two hours until he had taken two drachms. The bleeding never recurred. In another case, after the extraction of a tooth, the bleeding was arrested by the administration of opium, but returned on the following day, when the author gave the patient calcium chloride, and by evening the bleeding had stopped. In this case the use of calcium chloride was continued for three days. In the third case, vomiting of blood had gone on all night, and every native remedy had been tried unsuccessfully. The author gave some soap pills, and, as the patient was very anxious and restless from the loss of blood, he told him that the bleeding would not return after swallowing them. This was somewhat hazardous, Dr. Huntly remarks, but the diagnosis was clear that the hæmatemesis was due to an irritant powder swallowed by mistake. After using other measures and calcium chloride, there was no recurrence of the bleeding.

In a case of severe epistaxis the same measures had proved effectual without resorting to plugging. In cases of hæmaturia, in the author's experience, the use of opium has not been successful. In these cases, he says, the diagnosis is often obscure, and the practical value of opium in cases of uramic coma, in which it re-establishes the flow of urine, leaves the question of the mode of action of the opium on the kidneys still a subject for clinical investigation. In his cases opium was given to stem the bleeding for the time, and calcium chloride seemed to justify the statements put forward on theoretical grounds, for it promoted coagulation. Dr. Saundby, he says, has obtained good results in a case of purpura hæmorrhagica from six-grain doses of calcium chloride repeated every two or four hours. Dr. Huntly thinks better results are to be obtained from the combination than from either drug alone, although opium by itself has often proved successful, as Nature mends the broken surfaces while the opium is exercising its restraining influence; but when calcium chloride is added, Nature's efforts are supplemented. Opium acts on the smaller arterioles and capillaries, while calcium chloride acts through and on the blood, and the combination is all the more valuable because their spheres of action do not clash. As a combination, he thinks that calcium chloride and opium should be found superior to lead and opium.

The Disinfection of Rooms Infected with Tuberculous Products.—Professor Sheridan Delépine, of Manchester, in an article on this subject published in the Medical Chronicle for May, says that experimenters have shown that the action of a solution of chloride of calcium is almost universal and very rapid, that it is due to the liberation of chlorine, and that the presence of acids and elevation of temperature accelerate its

action. He gives an account of extended experiments, the results of which, he says, justify him in saying that the best method of disinfecting houses that have been contaminated by tuberculous patients is with chlorinated lime, which should be carried out in the following manner: 1. A solution of chlorinated lime (1 in 10) should be prepared. 2. The walls, ceilings, and floors should be washed with this solution applied in the same way as whitewash. 3. This process should, for safety, be repeated three or four times, starting each time at the same corner of the room, so that each layer will have time to penetrate into the paper and the woodwork and become partly dry before the next coating is applied. 4. The room should then be closed as well as possible, a small, safe petroleum stove being first placed in the middle of the room, and precautions taken to prevent any chance of fire. Over this stove a large tin basin full of water or chlorinated-lime solution should be placed. (By a simply devised water-bath arrangement, a small capsule full of strong acetic acid or hydrochloric acid might be placed over the boiling water, and in this way acidity of the air would be secured. This would cause a more rapid setting free of chlorine.)

In this way, says the author, disinfection should be completed in less than three hours. Some of the additional precautions which are recommended may not be absolutely necessary. The use of hydrochloric acid is the most objectionable addition from a practical point of view, for it causes great damage to metallic fittings. Chlorinated lime does not spoil things so much as would be expected, and can be used in rooms from which all hangings and carpets have been removed without any fear of damage, if the walls and ceilings are not decorated with valuable paintings or papers.

The New Hampshire Medical Society will hold its one. hundred-and third annual meeting in Concord, on Monday and Tuesday, June 18th and 19th, under the presidency of Dr. Samuel P. Carbee, of Haverhill. The programme includes the following titles: On the Prevention of Communicable Diseases. by Dr. D. Edward Sullivan, of Concord; Sleep, How Best Induced in Certain Pathological Conditions, by Dr. J. B. Raynes, of Lebanon; On Puerperal Infection, by Dr. J. Elizabeth Hoyt, of Concord; Retrospective Glances, by Dr. A. G. Straw, of Manchester; Bone Surgery, by Dr. D. S. Adams, of Manchester; Empyema, by Dr. William H. Lyons, of Manchester; On the Differential Therapeutics of Strophanthus and Digitalis, by Dr. W. K. Wadleigh, of Hopkinton; On the Pathology and Methods of Treatment of Hypertrophic and Atrophic Rhinitiswith Special Reference to the Work of the General Practitioner, by Dr. Albert Pick, of Boston; On Laceration of the Cervix Uteri, by Dr. F. A. Stillings, of Concord; Glimpses of Fifty Years in the Medical Profession, by Dr. Cyrus K. Kelley, of Plymouth; On Sanitation in Mexico, by Dr. G. P. Conn, of Concord; On the Importance of the Early Recognition of Certain Diseases of the Eye by the General Practitioner, with Suggestions regarding Management, by Dr. H. W. D. Carvelle, of Manchester; and the Discussion opened by Dr. George Cook, of Concord; president's address.

The Association of American Anatomists,—At the recent annual meeting the following new members were elected: Dr. John A. Roger, assistant demonstrator of anatomy, University of Pennsylvania; Dr. H. B. Ferris, assistant professor of anatomy, Yale University; Dr. Robert L. Greene, professor of anatomy, University Medical College and Western Dental College, Kansas City, Mo.; Dr. William Keiller, professor of anat-University of Texas; Dr. Joseph Leidy, assistant demonstrator of anatomy, University of Pennsylvania; Dr. Mary B. Moody, of New Haven, Conn.; Mr. Robert O. Moody, of | of the heart. In attacks that are very moderate in intensity,

Yale Medical School; Dr. Charles D. Smith, professor of physiology, Bowdoin College; Dr. William O. Stillman, of Albany, N. Y.; and Dr. W. C. Woodward, of the University of Georgetown, Washington.

The officers elected for the ensuing term were Dr. Thomas Dwight, of Harvard University, president; Dr. Burt G. Wilder, of Cornell University, and Dr. F. J. Shepherd, of McGill University, Montreal, vice-presidents; Dr. D. S. Lamb, of the Army Medical Museum, Washington, secretary and treasurer; Professor C. L. Herrick, of Denison College, Granville, O., delegate to the Congress of American Physicians and Surgeons; Dr. D. K Shute, of Columbian University, Washington, alternate: and Dr. Theodore M. Gill, of the Smithsonian Institution, Washington, to fill a vacancy in the executive committee.

The Treatment of an Acute Attack of Hepatic Colic .-

Dr. A. F. Plicque, formerly an interne of the Paris hospitals, discusses this subject in the Gazette médicale de Paris for May 26th. An attack of hepatic colic, he says, may present itself under one of two forms: 1. The very acute form, exceedingly painful, which fortunately is not usually of very long duration. 2. The more subdued form, apparently more easily borne, but in which the paroxysm is more prolonged, and after which a discouraging succession of attacks often In the former the prime indication is to allay the pain. In the second form the most important indication is to facilitate the passage of the calculus. In the very acute form the chief complications are ungovernable vomiting, paresis of the heart, and reflex pulmonary congestion. In the prolonged form chief attention should be paid to the danger of biliary infection. In the absence of reflex complications, many others of a mechanical nature may supervene relating to the incarceration or the faulty direction of the calculus, but their treatment is rather that of biliary lithiasis than that of an attack of hepatic colic. In attempting to allay the pain in an acute attack we can not, owing to the vomiting, count upon medicines given by the mouth. External anodyne applications produce hardly any relief. Compresses moistened with chloroform give rise to tolerably lively rubefaction, and are somewhat more efficacious. Very hot poultices moistened with forty drops of laudanum may also be tried, but applications of ice should be avoided. The principal measures are enemata of chloral and laudanum and subcutaneous injections of morphine. The chloral enemata should be rather concentrated. As an example, the author suggests one composed of thirty grains of chloral bydrate, the yolk of an egg, and four ounces of warm water. The opiated enema may contain twenty drops of laudanum in an ounce of water. As under other circumstances, a large warm enema should be given before the one that is medicated. These in themselves have a perceptible sedative action. The use of subcutaneous injections of morphine should not be resorted to until the measures previously mentioned have failed. and for the first dose, in a patient not accustomed to the drug, an eighth of a grain should not be exceeded, and atropine should not be added to the solution of morphine unless the liver is performing its functions well. Sometimes morphine in-

creases the vomiting, and sometimes it is powerless to allay the

atrocious pain; in that case it becomes necessary to resort to

inhalations of chloroform. In less acute attacks we may give

syrup of chloral, antipyrine in doses of from thirty to sixty

grains in the course of twenty hours, or pills containing an

eighth of a grain each of extract of belladonna and extract of

opium, of which eight or ten may be taken in the course of

twenty hours. Warm immersion baths lasting for an hour are

very useful, but they are contraindicated in cases of weakness

but prolonged, external applications are preferable to narcotics given internally. Applications of Pacquelin's cautery over the region of the liver, or in vigorous subjects the application of a few leeches, often give great relief. If the pain that radiates to the right shoulder is particularly severe, it will be well to apply methyl chloride in the form of spray or by painting it on-This drug has indeed been applied directly to the region of the liver itself with success.

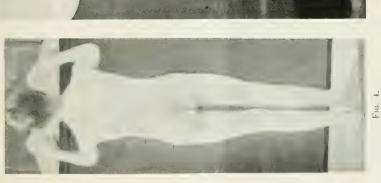

Three drugs are of use in facilitating the expulsion of the calculus. They are olive oil, glycerin, and amylvalerianic ether, Violent purgatives are to be avoided, for they would frequently cause such accidents as the incarceration of the calculus and rupture of the biliary passages. Cautious massage is soothing to the patient and is free from danger, but not much reliance is to be placed on it as an agent for facilitating expulsion. The use of electricity is to be avoided. Olive oil may be given to the amount of six ounces in two portions, a quarter of an hour apart. It must be of very good quality. After having taken the oil, the patient should remain lying on his right side for several hours. In case the oil is very repugnant to the taste, it may be administered through a stomach-tube; given in this way it is not so apt to be vomited as when it is taken directly by the mouth. Glycerin should be given in large doses, as much as from an ounce to an ounce and a half, and the best way of administering it is in a glass of Vichy water. Amylvalerianic ether has been recommended by Chauffard in doses of from four to six capsules [the amount of the contents not specified] in the course of twenty-four hours. Its action seems to be superior to that of the old mixture of ether and oil of turpentine.

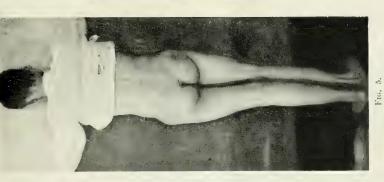

As regards the complications, vomiting should be treated by the ordinary measures, such as Seltzer water, grog, iced champagne, and potio Riverii [made by mixing equal parts of a solution of two parts of potassium bicarbonate in fifty of water with fifteen of sugar and a solution of two parts of citric acid in fifty of water with fifteen of syrup of citric acid]. If the vomiting is prolonged and interferes with the ingestion of the necessary amount of food, an attempt should be made to nourish the patient by means of a tube. Counter-irritation over the liver is often very efficacious. Weakness of the heart should be treated with stimulating frictions, dry cupping, etc. Digitalis should not be used. In case there is a tendency to syncope, subcutaneous injections of caffeine may be employed, four grains at a time, from two to four times a day. These injections of caffeine may be alternated with injections of camphor. Thirty grains of camphor may be dissolved in two drachms and a half of sterilized olive oil, and from one to three syringefuls of the solution may be given in the course of a day. Pulmonary congestion may be combated by the semi-recumbent or the lateral-recumbent posture, and especially by the application of dry cups. In such cases antimonials should be avoided. Alcohol in moderate doses is very useful. In case of fever, indicative of biliary infection, intestinal antisepsis should be attempted, For this purpose salol is the best agent. It may be given in daily amounts of from thirty to sixty grains, in capsules of seven grains each. The patient should take a large glass of milk after each meal. Constipation is to be combated, not by violent purgatives, but by gentle laxatives, such as saline waters in small doses, with a mild preparation of jalap and pills of an eighth of a grain each of extract of opium and extract of hyoscyamus. Prudence should be exercised in the administration of calomel, which at first sight seems indicated as a cholagogue, as a purgative, and as an antiseptic. The flow of bile which it provokes often increases the colic. As a remedy for the fever itself, we may employ sulphate of quinine, preferably in the form of suppositories or enemata. Salicylate of sodium, to the daily amount of from forty-five to sixty grains, appears to have a special action against biliary fever. In some cases it seems also to aid in allaying the pain. In case the salicylate fails, we may try tincture of boldo, from ten to thirty drops daily. The action of the skin should be kept up carefully. The diet should be restricted to milk and vegetables, and it may be useful to add to the milk some alkaline water, such as that of Vals or Vichy.

"Falling of the Palate."-The Journal des sciences medicales de Lille for April 14th publishes an article on this subject in which the author gives a brief account of his experience in cases of this kind. "Falling of the palate," he says, plays an important part among the common people; all affections of the mouth or the throat which can not be accounted for by cold are attributed to prolapse of the uvula, or, as they call it, "falling of the palate." Often, he says, patients have come to him and said that they had a sore throat, that they could not swallow, and consequently that they thought they had "falling of the palate." In spite of himself, he continues, he has burst out laughing before the scandalized patients, and all his attempts to dispel such an idea have proved unavailing, for they still persisted in it. One patient asserted that a midwife had told her so, also that her child had had it for six months, and would have been ruined if the midwife had not put the palate back again into place. There are specialists for this mysterious operation, midwives and old women, who make a reputation in this particular branch. They carefully support and encourage this idea, the former because of the material profit accruing from it, and the latter partly because they like the work and partly because they gain a certain glory from it. It is therefore not to be wondered at, says the author, that he can not convince his patients to the contrary. It seems to him good policy to make some concessions, so he willingly agrees with his patients that the palate has really been somewhat displaced, but that, nevertheless, there have been other troubles, such as angina, laryngitis, etc., thus sparing the patients' feelings and their cherished tradition; then too, he says, his own medical convictions are not seriously disturbed.

Prolapse or hypertrophic prolongation of the uvula has no significance in pathology except to explain certain rebellious coughs produced by tickling at the base of the tongue, and all other troubles attributed to it are due to the old tradition and to human folly. The author cites the following instance: One evening a man entered his office hastily, apparently in great terror, for his face was pale and his eyes were wild and haggard. He told the author, with much difficulty, that he could not speak, that he was suffocating, and that he did not know what he had in his throat, but that some one had told him that his "palate had fallen down." All this time a bloody, sticky, and viscous saliva ran abundantly from his mouth. On examination, a cylindrical body about two centimetres in length was seen at the bottom of the throat; it was as large as the little finger, of a livid, violaceous color, and surrounded with bloody mucosities. It was the uvula which had become enormous. Naturally very long in this man, it had become ædematous under an attack of angina, and, probably in an effort to cough, it had become bent at its junction with the velum palati in such a manner as to make it protrude directly forward into the buccal cavity. The writer pushed it back, which at once allayed the great fear under which the man had evidently been laboring, and thus the author, although not a specialist in such matters, had replaced the "fallen palate." Perhaps, he says, his colleagues will say that it is a loss of time to turn one's attention to such trifles, which are not worthy of appearing in

OBSERVATIONS ON

# BENDING OF THE NECK OF THE FEMUR IN ADOLESCENCE,

WITH PARTICULAR REFERENCE TO THE DIAGNOSIS AND SIGNIFICANCE OF THE AFFECTION.\*

BY ROYAL WHITMAN, M. D., M. R. C. S.,

CLINICAL INSTRUCTOR IN ORTHOPÆDIC SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; LECTTRER ON ORTHOPE-EDIC SURGERY AT THE NEW YORK POLYCLINIC.

It is proposed in this paper to call attention to a deformity at the hip joint that develops in adolescence under the same conditions as the other more familiar deformities of the lower extremity, most often in those who, at a period of rapid growth, of weakness and instability of the bones, are subjected to overwork or strain by occupations that require long standing or the carrying of heavy weights.

In this sense overwork is a relative term, since only a small proportion of individuals in a particular occupation break down, while similar deformities may appear in those who have not been subjected to these exciting causes. In many instances, therefore, one must recognize predisposing causes to satisfactorily explain a given deformity—such as the assumption of improper attitudes; or an inherited predisposition to deformity; or actual weakness of structure, either general or local; or slight deformities acquired in childhood, the effect of weakness or rhachitis, or of injury or disease, which increase under favorable conditions in later life.

The effect of this disproportion between the work to be performed and the strength of the supporting structures is most often seen in the member subjected to greatest strain in the production of flat-foot, which, indeed, may develop at any age and under a great variety of conditions; less frequently in distortion at the knee, and far less often in bending of the neck of the femur, which may or may not be associated with the preceding deformities.

The symptoms of this type of progressive deformity of the lower extremity in adolescence vary according to the function of the joint affected, the rate of progress, the extent and duration of the deformity, the secondary changes induced, and their effect upon the gait and posture of the individual; but, in general, they are weakness, awkwardness, local pain on exertion, and stiffness in the affected joint in changing from a period of rest to activity.

It is the pain of flat-foot, not the deformity, which impresses the patient. At the knee joint it is the deformity, not the pain or disability, for which advice is asked, and in the analogous deformity at the hip it is often the disability, rather than pain or deformity, that attracts attention.

It is only in very recent years that an affection so common as flat-foot has been generally recognized or treated by physicians, and it is therefore not strange that a com-

\* Read before the American Orthopædic Association, at Washington, May, 1894.

paratively rare condition, in a joint so deeply seated and concealed by overlying muscles, has attracted so little notice.

In 1889 E. Müller\* reported four cases of bending of the neck of the femur as a new type of disease, of which the symptoms were presented as follows:

In adolescence, without apparent cause or following slight injury, the patient begins to limp and to complain of fatigue and pain about the affected joint on exertion. Shortening of the limb is soon apparent, and is caused by elevation of the trochanter above Nélaton's line. The limb is usually slightly rotated outward, extended, or slightly flexed. The motion of the joint is somewhat limited, particularly in abduction; there is no local swelling or tenderness on pressure.

The ages of the patients reported were sixteen, seventeen, eighteen, and nineteen years, and in all the deformity was on one side only.

A specimen of the deformity was in one case obtained by resection. The joint surfaces were found to be perfectly normal; the neck of the bone was depressed to a right angle with the shaft (Fig. 1). Section showed no evidence

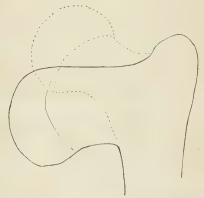

Fig. 1.—Outline of the depressed neck of the femur in Müller's specimen, contrasted with the normal position shown by the dotted line.

of disease or change other than that of the internal structure, according to the altered condition of weight and function.

Shortly after the publication of Müller's paper, Rotter † presented to the Medical Society of Munich a case of bending of both femoral necks in a boy of fifteen. The symptoms were fatigue and pain on exertion, an awkward rolling gait caused by adduction of the limbs, prominent trochanters elevated above Nélaton's line, and moderate restriction of motion. No evidence of local disease was present.

A specimen of very great deformity of the neck of the

<sup>\*</sup> Ueber die Verbiegung des Schenkelhalses im Wachsthumsalter. Ein neues Krankheitsbild. Beiträge zur klin. Chir., 1889, Bd. iv, S.

<sup>†</sup> Ein Fall von doppelseitiger rhachitischer Verbiegung des Schenkelhalses. Münchener klinische Wochenschrift, Aug. 12, 1890.

femur was obtained by Hoffa\* by resection of the joint. The patient, a girl of fourteen, had begun to limp at the age of three years without known cause; shortening of the leg had steadily increased, unaccompanied by any symptoms other than limp and fatigue on exertion. The appearances were somewhat like those of congenital dislocation of the hip—great prominence and elevation of the trochanter to seven centimetres above Nélaton's line; no marked restriction of motion in any direction.

The joint was normal, but there was such depression of the neck of the femur downward and backward that the head of the bone rested on the trochanter minor at an angle of 60° with the shaft as contrasted with the normal of 128° (Fig. 2). Section showed change in structure but no evidence of previous disease.

Fig. 2.—Outline of the deformity in Hoffa's specimen. The dotted line shows the normal position.

These cases represent the meager literature of the subject which has apparently attracted no attention in this country up to the present time.

During the past two years four examples of this affection have come under my observation.

I present the histories of the patients, somewhat in detail, with photographs showing the appearances and effect of the deformity, in the hope that one of the obscure affections of the hip joint may be recognized and more effectively treated than under such diagnoses as periostitis, tumor, dislocation, rheumatism, hip disease, or paralysis, as in some of the cases to be reported.

Case I.—A well-nourished boy, fifteen years of age, came to the Hospital for Ruptured and Crippled on June 7, 1892. There was a marked limp on the right side and evident shortening of the leg, for which a high shoe was worn.

One year before, without known cause and without symptoms, a gradually increasing limp was noticed, and in six months it was necessary to apply a cork sole to the shoe to compensate for the shortening of the leg.

On examination, the appearances were those of congenital dislocation of the hip—that is, a very prominent trochanter elevated upward and backward, above Nélaton's line.

The actual shortening, measured from the anterior superior spine to the internal malleolus, was three quarters of an inch. The apparent shortening, measured from the umbilieus, caused by the adduction of the limb was three inches and a half. The position of the foot was normal. There was no limitation of flexion, extension, or rotation of the limb; the movements were free, smooth, and painless. Abduction was absolutely restricted. That the head of the bone was in the acetabulum was shown by its normal motion and because it could not be moved up or down from its position by pressure or traction.

[N. Y. MED. JOUR ..

During the two years intervening between the first examination and the present report, the boy has been examined from time to time at his home. The appearances noted at the first examination have become gradually more marked. The actual shortening of the leg had increased an inch in April, 1893, and to an inch and a half in April, 1894; the trochanter has become more and more prominent, until the deformity is as seen in the photograph presented (Fig. 3), which shows the adduction of the leg, the compensatory upward tilting of the pelvis, and the lateral curvature of the spine.

The patient has worked steadily at his occupation of driver of a peddler's cart; he insists that he has never suffered the slightest pain or discomfort, that his ability to walk and run is equal to that of other boys. His relatives and friends have been carefully questioned, but no variation from the history has been obtained. He was in perfect condition until the age of fourteen years. The limp and shortening began without apparent cause and have increased without symptoms. All treatment has been refused. He denies overwork or injury at any time, and there is no evidence of former or present rhachitis

CASE II.—The patient, a well-nourished boy of sixteen years, came to the hospital in July, 1893. Except for a somewhat exaggerated eversion of the feet and evident flat feet, there was nothing peculiar in his appearance.

In infancy he was said to have had weak ankles, and the flat feet were of indefinite duration, but had never caused pain or discomfort. For about two years he had been working as a grocer's boy, standing and carrying heavy weights. The previous spring he had been troubled with a peculiar soreness and stiffness about the right hip, thought to be growing pain. These symptoms were entirely relieved by a journey to Canada on a canal boat. On his return his usual work was resumed, and soon after the discomfort became again apparent, and had slowly increased during the winter; recently similar symptoms had appeared on the opposite side.

The symptoms complained of at this time were a feeling of fatigue and of pain referred to the right trochanter and to the front of the thigh; a peculiar stiffness about the hip after sitting or remaining long in one position. The symptoms were increased by extra work, diminished by rest; there was at no time pain when at rest.

On examination, the eversion and flatness of the feet were very apparent, there was slight knock-knee, slight hyperextension at the knees. The trochanters appeared slightly elevated above Nélaton's line (Fig. 4) and somewhat forward of their ordinary position. The gait was somewhat rolling in character; the motion at the hip joints was perfectly free in flexion and extension, abduction limited to about a third of normal, rotation inward limited with the feet in the perpendicular line. The restriction was somewhat greater on the right side than on the left, and there was slight atrophy of the muscles of the thigh. The diagnosis of bending of the femoral necks was made; rest, gymnastic exercises, and tonics were advised.

No particular notice appears to have been taken of the diagnosis or advice, for three months later he again appeared at the hospital, at this time able to walk only with much effort, the body swaying from side to side in a very marked and peculiar

manner. A number of physicians had been consulted in the meantime, diagnoses varying from hip disease to paralysis having been obtained.

On standing, the prominent trochanters were seen to be markedly elevated above Nélaton's line (Fig. 5), and nearer the median line of the body—that is, although the patient stood with the feet greatly everted, the trochanters were in the position that they should have assumed with the feet inverted. Behind each trochanter there was a deep sulcus; the normal lumbar lordosis was absent; abduction of the legs now limited at the line of the body; flexion of the legs only possible when they were crossed (Fig. 6)—that is, flexion increased the adduction.

Extension of the limbs free; flexion somewhat limited on the right side; no pain or spasm or interference with motion within these limits. Crutches were now ordered.

The patient was again seen at his home four months later, and a final examination was made on May 1, 1894. The adduction had increased so that the patient swung himself along on crutches, the left leg crossed over the opposite. It was only with the greatest effort that the legs could be passed by one another, so that he usually hitched along with one leg behind the other—the so-called scissors walk.\* One very noticeable change has taken place: the progress upward of the trochanter on the left side is no longer forward but upward and backward; the pelvis is thus slightly twisted, and, as the weight falls somewhat behind its normal axis, the lumbar lordosis, absent at the first examination, is now well marked. There is a compensatory upward tilting of the pelvis on the left side.

When lying on the back the eversion of the right leg is so great that the outer border of the foot rests on the table. Inward rotation is possible to 45° only. On flexing the right thigh, the leg crosses that of the opposite side, and with the thigh at a right angle with the body the outward rotation is so great that the heel is in the line of the opposite anterior superior spine. The outward rotation is less on the opposite side, but the adduction is about the same—that is, about 15°. With the limbs parallel and extended, separation of the knees to three inches and a half only is possible. Flexion at once crosses them, which explains the peculiar walk. The trochanters are at least an inch and a half above Nélaton's line.

As the patient stands, the broadening of the pelvis and shortening of the legs relative to the body is evident (Figs. 7 and 8). He is in perfect health and has no pain; although he has grown very rapidly during the year, the legs measured from the anterior superior spines to the internal malleoli are apparently of the same length as at the first examination, the increase in growth being compensated by the upward displacement.

It is believed that the bending of the necks has nearly reached the limit, and it is proposed during the summer to divide the femora below the trochanters so that sufficient abduction may be acquired to make walking possible. The photographs show the condition very well.

Case III.—An overgrown German boy, seventeen years of age, applied at the Vanderbilt Clinic on March 1, 1894. He had for a year been working as a baker; the hours were long, and he was obliged to stand constantly. Within the year he had noticed a bending of the right knee and a peculiar stiffness and pain about the left hip and thigh, most marked on changing from a position of rest to activity, as on rising in the morning or after sitting. Examination showed well-marked knock-knee on the right side (Fig. 9), and at the opposite hip joint restriction of abduction and slight restriction of inward rotation of

the leg; slight elevation of the trochanter and approximation toward the median line. The limb was three quarters of an inch longer than its fellow, as measured from the apices of the trochanters to the soles of the feet, so that no actual shortening was apparent. The treatment consisted in absolute cessation of work, regular gymnastic exercises, massage, and stretching of the affected hip and knee. All the pain immediately ceased.

Case IV .-- A healthy, well-nourished Italian boy, aged eleven years, came to the hospital on March 20, 1894, saying that he had been sent by his Sunday-school teacher because he limped. This limp was of possibly one year's duration; there was also at times a feeling of stiffness and discomfort about the hip and front of the thigh after long standing and running at his occupation, that of newsboy; no pain when at rest. Examination showed slight limp, slight downward compensatory tilting of the pelvis, elevation of the trochanter to an inch above Nélaton's line, and prominence most marked on flexing (Fig. 10.) One inch shortening; no adduction; no pain on motion or spasm; slight limitation of inward rotation and of abduction. The symptoms and appearances simulated exactly those of fracture of the neck of the femur with upward displacement. As the boy and his mother, whom I afterward saw, thought the symptoms-that is, the limp and discomfort on exertion-were becoming more marked, it was decided to apply a traction hip splint to temporarily relieve the weakened bone from strain and pressure. This, combined with massage and exercises, relieved the symptoms at once.

As photographs are presented of all the cases a more detailed description is perhaps unnecessary, nor have the various measurements been given, as it is thought that such details are of more importance in arriving at the diagnosis than of interest to the readers of the communication.

There is certainly a marked difference in the cases: Cases II and III show evidence of the weakness of adolescence in deformity of other joints and present also an exciting cause in the occupation.

In the first case no other joint is affected nor is there evidence of general weakness or exciting cause; although the deformity is greater than in the three other cases, the patient denies pain or discomfort.

From the clinical symptoms it would appear that the progress of the bending of the neck of the femur is comparatively rapid until the resistance of the compressed bone is sufficient to oppose further increase of the deformity, or until the head of the bone rests upon the trochanter minor, as in Hoffa's specimen.

Apparently the head of the bone is usually depressed downward and backward in the line of the least resistance; the femur is thus rotated outward, which explains the eversion of the feet; the trochanter elevated and pushed nearer to the median line of the body. Its prominence is explained by the elevation and by the change in the angle of the neck.

The limitation of abduction of the limb is explained by the pressure of the neck upon the upper border of the acetabulum, of the trochanter on its upper and posterior rim, and by the pressure of the lower border of the depressed head upon the lower portion of the capsule (Fig. 11). In other words, with the legs in apposition, the deformed neck is in the relation to the acetabulum that is

<sup>\*</sup> Petit. Les jambes en ciseaux. Cong. français des chiv., 1892, p. 733

normal in extreme abduction of the limbs. Flexion of the limb increases the deformity, as may be explained by the shape and position of the acetabulum; its upper and

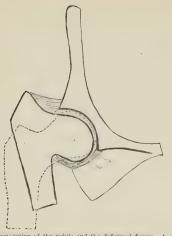

Fig. 11.—Cross section of the pelvis and the deformed femur. A scheme to show the effect of the deformity in limiting abduction of the limb. The dotted outline shows the normal relation.

posterior margin being more prominent, it interferes with the prominent trochanter, so that adduction is increased and the tissues are markedly distended by the projecting bone; thus the assumption of the sitting posture is often painful, or rather the change from the erect to the sitting posture. This symptom was complained of in the cases of fracture of the neck of the femur in young children which I have reported,\* in whom the deformity and clinical appearances were very similar to a slight degree of this deformity. If the deformity is of one side only, the symptoms are simply stiffness and limp from the shortening, increased by the adduction of the limb, which causes the compensatory upward tilting of the pelvis. If on both sides, the adduction of the limbs causes the peculiar rolling gait because of the interference of the knees. The deformity of one side may cause merely an awkwardness and limp, but on both sides it may disable the patient.

The character of the pain is similar to that noticed in developing knock-knee and bowlegs of adolescence. The awkwardness and weakness are sufficiently explained by the changed relations of the joint surfaces and of the muscles and ligaments attached to the femur. If the leg is greatly adducted as the result of the depression of the neck of the femur, the conditions are favorable to a gradual upward enlargement of the acetabulum, and it is possible that the final result in as extreme a case as No. 1 may be a partial dislocation from the acetabulum.

Although Müller was the first to call attention to the clinical significance of this affection the deformity itself has been described by several others. Röser in 1843 † de-

scribed a specimen obtained from a subject who died at the age of twenty-four years. During life the limb had been so adducted and flexed as the result of inflammatory disease in the neighborhood of the joint that it had never been used, and was supposed to be a deformity caused by spontaneous dislocation from hip disease. Section showed the joint surfaces normal and the head of the bone in the accetabulum, the neck being greatly distorted downward and forward.

Zeis, in 1851,\* described a museum specimen of distortion of the neck of the femur downward and forward, and in this case also section showed no disease.

A very perfect illustration of downward distortion of the neck of the femur to forty-five degrees may be seen in the Transactions of the Philadelphia Pathological Society for 1857,† obtained from a subject in a dissecting room. Before removal the deformity was supposed to be the result of fracture. Section showed no evidence of previous injury or disease. The opposite femur was deformed in a similar manner though to a less degree.

Another familiar example of change in the angle and position of the neck of the femur is that of congenital dislocation.

In each of the five instances in which I have had an opportunity to examine the neck of the bone during the operation for its replacement after the method of Hoffa it was depressed to a right angle with the shaft, and in one case markedly displaced forward.

Specimens show depression of the neck as the result of fracture and of local disease, as in osteomyelitis, † osteitis, or necrosis, and one case of very great deformity of both femoral necks somewhat resembling in clinical history Case II was described and illustrated by Monks,# of Boston, in 1886. Although the patient, a boy of eighteen years, suffered from knock-knee and flat feet in addition to deformity at the hip joint, it did not occur to the author, nor to the gentlemen who discussed the case, to include the deformities under one general cause. Dr. Monks was obliged to make the evidently unsatisfactory diagnosis of arthritis deformans to explain the peculiar deformity at the hip. A case somewhat similar in history and appearance to that of depression of the neck of the femur has been reported and illustrated by C. B. Keetley, | of London, to whom I am indebted for the original manuscript and photographs of the case. The patient, a girl of twenty, was admitted to the West End Hospital in March, 1888, for a limp and marked prominence about the right trochanter. The duration of the deformity was about eight years; she had been treated at various hospitals from time to time under diagnoses of dislocation, periostitis, tumor, and the like.

Keetley regarded the case as unique and called Sir James Paget in consultation, who did not make a diagnosis but advised observation.

Later, Keetley made a diagnosis of local rhachitic disease with bending of the femur in the trochanteric region, because of the slow progress of the disease and the development of a rotary curvature of the spine. As the disability was caused principally by adduction of the limb Keetley removed a cuneiform section of the bone below the trochanter and by division of the adductors brought the limb into good position with subsequent great improvement in the posture and gait. The subsequent history is not given. The wedge of bone removed at the operation showed evidence of local rhachitis.

Bending of the neck of the femur may be one of the deformities of osteomalacia, osteitis deformans, and finally, as the result of the very much more common disease, rhachitis.

Lauenstein \* obtained specimens of downward bending of both femoral necks from a child of six years, who died shortly after the rectification by osteotomy of other rhachitie deformities of the lower extremity. This peculiarity had not been suspected during life. He afterward examined several adult skeletons deformed by rickets and in one found very great distortion of the femoral necks, the trochanters being in such close proximity to the rim of the acetabulum that slight motion only could have been possible during life.

Nélaton † called attention to the occasional elevation of the trochanters in rhachitic children. I have examined a large number of rhachitic children with reference to this point.

The elevation of the trochanters, when present, is usually either apparent, due to the abduction of the limbs, as in bowlegs, or in other instances seems to be caused rather by an outward bending of the upper part of the shaft than by change in the angle of the neck. In one case, a child of two years, suffering from a mild degree of rhachitis, elevation from bending of the necks appeared to be present, and there was in addition the characteristic limitation of abduction of the thighs, a symptom absent in the other children examined. The legs were nearly straight; the principal symptom, according to the mother, was the difficulty experienced by the child in getting on its feet from the sitting posture.

It is evident, however, that this deformity in early childhood is a rare one compared with the other deformities of rhachitis, probably because the neck of the femur is so short and comparatively large that bending to the extent of producing noticeable and characteristic symptoms is hardly possible.

The question of actiology of the deformity is naturally of importance in its influence on the treatment to be pursued. Müller thought that a local form of late rickets would best explain the weakness of the bone, and this view is supported by Lauenstein.

The term "late rickets" is a misleading one, because it is applied by Clutton,\* Drewitt,† and others to a general disease identical with infantile rickets that may appear in later life, as shown by cases and specimens obtained.

Local rhachitis, in the sense used by Müller and others, has none of the characteristics of ordinary rhachitis, either in symptoms or in the appearance of the specimens.

Mikulicz, it is true, supported the theory of local rhachitis as the cause of similar deformities at the knee joint by the broadening of the epiphyseal cartilage, a condition which Trippier asserts is normal at a period of rapid growth.

As there is at present no direct evidence of local rhachitis, it may be well to call attention to other possible predisposing causes for this deformity; for example, relative slenderness and weakness of the bones, to which attention has been called by Mikulicz, Arndt, and Humphrey; to the variation in the angle of the neck of the femur between 110° and 140° in the specimens examined by Humphrey and Mikulicz; also in its direction. Usually it projects forward from the shaft at an angle of 12°, but in certain specimens this was increased to 20°, and in one it projected backward at an angle of 25° with the shaft.

Some of these peculiarities I have noticed in the dissecting room of the College of Physicians and Surgeons, especially the variation in the size and apparent strength of the neck in bodies of corresponding size.

Humphrey ◊ asserts that there is not, as is usually supposed, a gradual sinking of the neck from childhood to old age, but that the descent is terminated in adolescence. This statement is supported by the observations of Lane. ‡ If it is true that a certain amount of depression of the femoral neck is normal during adolescence, it seems reasonable that this may become exaggerated to deformity in individuals presenting possibly peculiarities in the shape. size, or position of the bone, or in those subjected to some of the other predisposing causes which have been mentioned. It is possible also that injury, as suggested by Müller, or sudden overexertion, as in a case reported by Mosetig, may in certain instances serve as the exciting cause of the deformity. Although rhachitis is responsible for most of the extreme deformities of childhood, yet it is a matter of common knowledge that bowleg is not at all uncommon in children who do not show a trace of disease -who are, in fact, exceptionally active, standing and walk-

ing at an early age—the bending of the bone being in such cases the effect of over-weight.

It is, however, not the object of this paper to deny the possibility of rhachitis as the cause of this affection, but rather to place this particular deformity in the same class with the knock-knee and bowleg of adolescence.

The treatment, aside from that of the general condition, will be: 1. To remove the exciting cause—that is, overwork. It may be in some cases that simple cessation of the occupation will be sufficient; in others, and particularly the one-sided deformity, the long traction hip splint, if the patient will permit, would seem to be indicated.

- Local massage, exercises, and manipulation and passive motion in the direction of the restricted motion, on the principle of manipulation in the treatment of similar deformities of the knee and foot.
- 3. In the advanced cases osteotomy below the trochanter, on the principle followed in deformities at the knee, because the disability is caused by the adduction of the legs more than by actual shortening. By osteotomy, with consolidation, with the legs widely separated, one may, to a certain extent, replace the head of the bone in a relatively proper position and relieve the extreme outward rotation. The diagnosis of the affection does not offer any particular difficulties at the stage in which patients usually present themselves.

Marked prominence and elevations of the trochanter above Nélaton's line can be caused only by these conditions:

- Displacement of the head of the bone from the acetabulum.
  - 2. Change in the angle of the neck of the femur.
- 3. By upward enlargement or "wandering" of the acetabulum.

Dislocation may be congenital, in which case the patient limps from the moment that he begins to walk. It may be the result of traumatism, in which case the deformity and disability are instantaneous.

It may be the result of sudden distention and rupture of the capsule by serous effusion, as in rheumatism; or by pus, as in acute arthritis or hip disease.

All these conditions may be excluded by the history.

In the absence of any history, the differential diagnosis between dislocation and bending of the neck of the femur is easily made.

In all cases of dislocation of the femur upward, if the thigh is flexed and adducted to its extreme limit, the neck of the displaced bone can be traced upward and the head of the femur made out, moving beneath the distended soft parts when the thigh is rotated. In bending of the neck of the femur nothing but the prominent trochanter can be felt. In all cases of congenital dislocation a certain amount of upward and downward motion may be obtained by pressure and traction of the limb; in bending of the neck this is impossible.

The neck of the bone may be depressed as the result of fracture, in which case there is a history of injury. It may be distorted by local disease—as osteomyelitis, osteitis, or necrosis—when there must be the evident signs of local

disease, such as pain, swelling, suppuration, and constitutional depression. It may be depressed as one of the deformities of a general disease, such as osteitis deformans, osteomalacia, or general rhachitis. It is then but one of a series of deformities, and does not call for special comment.

Wandering of the acetabulum has only been observed after long-continued deformity and spasm of muscles, the result of confirmed hip disease, and the condition may therefore be excluded on the same grounds. It is evident that the only difficulty in diagnosis must arise at a very early stage of the affection from mild forms of rheumatism or hip disease. It is probable, however, that the progress of the deformity is coincident with the symptoms, thus differing from rheumatism, in which there is no elevation of the trochanter; and hip disease, in which elevation of the trochanter is a late symptom, occurring long after the diagnosis has been made.

In bending of the neck of the femur there is no local swelling or infiltration; the limitation of motion is in abduction and inward rotation; other motions are at this stage unlimited. In hip disease or rheumatism, when limitation occurs, it is in all directions, and accompanied by muscular spasm, which is absent in this affection.

The character of the symptoms, discomfort, stiffness, and pain about the trochanter and front of the thigh, increased by work and absent when at rest, is very different from the neuralgic pain of hip disease, while chronic rheumatism in a young person, confined to one joint, must be a very rare affection.

Prognosis.—Unchecked, the deformity shows a marked tendency to increase, as illustrated by Cases I and II. Judging from Müller's three cases, the pain, disability, and limitation slowly increase for a time; then the pain ceases, and the disability caused by shortening and restriction of motion remains, but does not prevent the patient from following his ordinary pursuits.

Doubtless early diagnosis and treatment will, in patients willing or able to follow advice, prevent the further increase of the deformity. Osteotomy, I am sure, will remove the more serious disability, although it can not be as effective as in the other deformities of the lower extremity.

The Treatment of Hiccough with Snuff.—In the Journal des praticiens for May 5th (Lyon médical for May 20th) M. Tatevossow relates a case in which he successfully combated diaphragmatic spasm accompanied by cough or prolonged paroxysms by making the patient take snuff until sneezing set in. Its action was immediate, the paroxysm ceased, and the continued use of the snuff caused the disease to disappear. This, it is remarked, is an extenuating circumstance in favor of snuff that the societies against the abuse of tobacco might take into account in their proceedings.

An Effervescent Purgative Lemonade.—The Journal des praticiens for May 30th publishes the following formula, by Dr. Constantin Paul, who recommends it on account of its rapid action (in two or three hours) and its being tolerated: Sodium phosphate, three hundred and seventy-five grains; distilled water, eight ounces; syrup, an ounce; tincture of lemon, twenty-five drops; citric acid and sodium bicarbonate, each, half a drachm.

# TWO CASES OF MALIGNANT DISEASE: AN OSTEOSARCOMA INVOLVING AN ANTERIOR CRANIAL FOSSA, AND AN EPITHELIOMA OF THE LARYNX.\*

BY CHARLES PHELPS, M.D., SURGEON TO BELLEVUE AND ST. VINCENT'S HOSPITALS.

In December last I presented to this society an intraperitoneal sarcoma which was of more than usual interest in its origin and development. The operation was immediately successful, and I have not at the present time been advised of its recurrence. I propose now to submit two other cases of malignant disease which, though differing from the first and from each other in type, have a character in common, in virtue of which they may be considered closely enough connected to form at least a harle-quin series.

A Case of Osteosurcoma involving an Anterior Cranial Fosset.—The patient, sixty-five years of age, was admitted to Bellevue Hospital in June, 1892, for relief of a pain in the left eye and frontal region. Ten months previously she had been knocked down, and, her forehead striking the floor, a persistent swelling over the left eye ensued, which gradually hardened, increased in size, and became moderately painful. In time it was followed by protrusion of the eye and lacrymation. Her general health was good and her previous history unimportant.

At the time of admission the eye was markedly protruded, but there was no evident change in its structure; sight was unimpaired. Ophthalmic examination disclosed slight optic neuritis. The osseous tumor was situated just above the external portion of the supra-orbital ridge; it was hard, painful on pressure, circular in form, about an inch and a half in diameter, and elevated above the surrounding surface about a half to three quarters of an inch at its highest point in the center. The skin which covered it was uninvolved. Its growth was very perceptible during the week's time in which it remained under observation.

In operation a semicircular incision was made from a point over the junction of the inner and middle thirds of the supraorbital ridge to the temporal fossa, and the underlying portion of the frontal bone exposed. This flap, with the eye and appendages, which were partially detached from the orbit, was turned over upon the cheek. The external table of the bone covering the tumor was thickened, softened, and eroded, and its margin well defined. A canal was then cut through the adjacent healthy bone, which was of unusual thickness-at least half an inch by actual measurement. A small trephine, Hay's saw, and rongeur were employed for the purpose. The orbital ridge internally and the malar process and zygoma externally were sawn through and the superior wall of the orbit exposed and cut. An attempt was made to lift out the mass by means of a curved periosteal elevator, which was successful only in removing its superficial portion; the remainder was subsequently excavated by the same instrument.

The operation, which presented no special difficulties, was completed in a little more than an hour's time. There was no loss of blood except a small amount from the tumor itself at one point at an early stage of the procedure, and which was readily controlled by a temporary compress of gauze applied beneath

the margin of the osseous incision. No stimulant was required and the patient did not suffer from subsequent shock.

The cavity which remained showed a loss of almost the entire upper and inner walls and a portion of the outer wall of the orbit, including the lacrymal bone and portions of the frontal sphenoid and ethnoid bones which had been incorporated in the process of growth. The tumor, apparently beginning in the diploe of the ascending frontal bone, had destroyed a great part of the external and all the inner table in the region where it had first appeared above the eye. It had then extended quite to the median line behind the orbit and beneath the frontal lobe of the brain. The dura mater was not involved and was uninjured in the course of operation. The whole left frontal lobe was exposed anteriorly and inferiorly, and could be seen to be compressed and pushed backward almost to the petrous portion.

The tumor was of irregular form, and from two to three inches in its longest diameter. It was largely composed of bone in lamellæ and tuberculæ, which were in great part eburnated. It was friable, but little vascular, and in its soft parts of cheesy appearance. A subsequent microscopic examination by Dr. J. W. S. Gouley showed it to be spindle-celled, with a small proportion of round cells intermixed. The adjacent muscular and connective tissue were infiltrated with the round cells. At the first dressing of the wound on the second day there was copious hæmorrhage, which seemed to be capillary and was readily controlled. Vision and ocular movements were both undisturbed, and there had been no elevation of temperature. At the end of ten days she became delirious, with lucid intervals, and complained of headache and photophobia. About this time she had two attacks of severe vomiting, followed by unconsciousness and apparent collapse. The condition of the wound, however, continued to be satisfactory, and the temperature at no time exceeded 100° F. Ten days later still the wound was almost entirely healed, and a plate of new bone covered in the cavity left after operation. Active delirium had ceased, but her mind was still unbalanced. She had some delusions, talked much to herself, was childish in her manner, and still complained of headache. At the end of a month there were no symptoms, either general or local. She was discharged from the hospital three months after the operation. The movements of the eye were unimpaired, and its structure and function were normal. There was no evidence of a recurrence of the disease. A thick, firm plate of new bone replaced the osseous structures removed. This presented a plane surface, as no effort had been made to preserve the frontal convexity, but no considerable deformity

Nothing occurred to attract the patient's attention to herself till December (six months), when she noticed a slight bulging of the eye, which was somewhat sensitive to the touch, and she began to suffer pain in the median line of the forehead. A little later she discovered a slight and very hard supra-orbital swelling, which, in six weeks' time, extended to the outer angle of the eye and over the malar bone. In March the swelling became less well defined and reached the temporo-parietal region. Vision was unaffected. She was readmitted to the hospital in April, 1893. At this time her general health had become seriously impaired. The frontal bone, at the inner margin of the former incision, was thickened and nodular. The tumor in the temporal region had increased and had softened so much as to give the impression of a cyst. The eye protruded, the conjunctiva was somewhat inflamed, and vision was a little clouded. She was feeble and anæmic, but her condition sufficiently improved in the course of a week to justify the attempt to again extirpate the tumor. Incision was made to circumscribe the cicatrix of former operation, beginning at the inner angle of the eye, carried well up toward the coronal suture, and

<sup>\*</sup> Read before the Society of Alumni of Bellevue Hospital, April 4, 1894.

terminated over the zygoma. The flap was dissected downward through the orbit, and with the eye, which was held only by the optic nerve and vessels, turned over upon the face, as in the original procedure. The frontal plate of new bone was cut, and the supra-orbital ridge at its inner extremity and the zygoma externally sawn through. The tumor was then removed in fragments by the bone forceps and the fingers. The dura was involved on the inferior cerebral surface, and at one point was torn away, exposing the brain tissue. The frontal lobe was less compressed than at the time of previous operation, and occupied about half of the anterior fossa. The portion of old frontal and ethmoid bone which had become implicated in the renewed progress of the disease was cut away. The new osseous growth, which had replaced the ascending frontal and orbital plate previously resected, was included in the mass removed. The present growth, unlike the original-which was dry, white, and cheesy, with osseous lamelle-was composed of delicate bony reticulæ, filled with soft and vascular tissue. Hæmorrhage was moderate, there was no shock, and strength was quite maintained by stimulants hypodermically administered during the operation. On the second day the conjunctiva and lids were somewhat ædematous, but vision was unimpaired. The optic nerve and retina, upon examination, were found to be much congested. On the fifth day some dysphagia and some rigidity of the right arm, which increased and then diminished, were noticed. Six hours later there was a slight convulsive movement of the whole left side of the body, and at about the same time a slight right façial paralysis was evident. Incontinence of urine and fæces followed. The left eye, which had become more protuberant, began to pulsate, and the cavity of the wound was found to be filled with brain substance. On the sixth day there were slight convulsive movements of the left side, with the general condition unchanged. On the seventh day the temperature increased (to 104.6°), the pulse became rapid, and respiration irregular and shallow. She died six days and seven hours after operation, having been unconscious for sixty hours.

Necropsy was denied. The wound was reopened, however, and the cavity left by removal of the tumor was found to be filled with diffluent brain matter, into which numerous minute hemorrhages had occurred. No foreign growth could be discovered in any part of the brain or cranial cavity which could be reached.

I have detailed this case with some minuteness because it seems to me of more than ordinary importance. The development of the tumor as a result of traumatism, its situation which came to be largely within the cranial cavity, the facility with which it was removed, and the apparent interval which elapsed before its recurrence, are alike worthy of note. The occasional origin of this form of malignant growth in traumatism is clearly illustrated, and the comparatively long period during which it seemed to be latent, although the adjacent tissues were infiltrated with small cells, is calculated to afford some confidence in operation even after the disease has made considerable progress.

Though the growth had its beginning in the diploe of the frontal bone, and was consequently originally extracranial, it was essentially intracranial at the time of operation and came within the province of that department of surgery. The method of procedure adopted demonstrates an easy means of access to the anterior portion of the cranial cavity for its complete exposure. The preservation

the eye and its appendages with entire integrity of func-

tion, and the reproduction of the frontal bone removed, obviate possible objections to its use.

The continued freedom of the brain from implication seems remarkable. For at least ten, and probably the greater part of twenty, months the dura had resisted the extension of the morbid process inward, though bone and connective tissue yielded. At the secondary operation the dura was found to be incorporated in the tumor over a very limited space, not larger than a finger nail. This was not from any inherent power of resistance, since in Hale White's collation of brain tumors sarcomata were more numerous than any others, save those of tubercular character, and some were of dural origin. Death finally resulted directly from brain lesion, but the sarcomatous growth was only concerned in so far as it induced fatal nutritive disorders.

Time only permits this very casual mention of matters which might properly deserve more careful consideration.

A Case of Epithelioma of the Larynx.—A gentleman of distinction in the medical profession, during a paroxysm of coughing three years ago, felt a rupture occur in the larynx and was aphonic from that moment until his death, though he suffered no other local inconvenience, and his general health until very recently remained unimpaired. In October, 1892, at my suggestion he consulted a specialist in diseases of the throat, who discovered a growth upon the left vocal cord which was of warty appearance and covered nearly its whole extent. He was assured that its character was benign and need cause him no uneasiness, but that he might return for further examination after some months.

In December last I visited him at his request. He had then been confined to his house since the first of the month, and thought he was suffering from the then prevailing epidemic of influenza. He was physically weak, mentally indisposed to exertion, and had some laryngeal cough. I subsequently learned that for some months he had subsisted mainly upon fluid food on account of a difficulty in deglutition, and had failed in nutrition. I attributed his condition to progress of the laryngeal tumor, and again suggested examination by a laryngologist. He was seen by Dr. C. C. Rice, who confirmed my suspicion that the disease was malignant, and coincided in my opinion that early tracheotomy should be done. In the early morning of December 31st the trachea was opened, partly on account of increasing dyspnea, but more hastily by reason of the unfavorable character of the pulse. He derived immediate advantage from this preliminary operation, which was soon lost by the considerable formation and extrusion through the tube of masses of tracheal granulation tissue. These contained aggregations of small spindle cells which were regarded as suspicious. On the 8th of February the larynx and trachea were opened externally in the median line from the thyreoid notch to the tracheal opening previously made. The tumor, which nearly filled the larynx, was cut away by seissors and its site curetted and afterward cauterized with chromic acid. The tracheal granulations were removed in the same manner. This operation, like the previous tracheotomy, was done with the use of cocaine and presented no difficulties, except in the control of some troublesome hæmorrhage from a small vessel at the posterior commissure of the vocal cords, which was finally effected by the fortuitous application of clamps which were left in situ overnight. I was assisted by Dr. Gouley, Dr. Rice, Dr. Wiggin, and Dr. D. H. Cooke, to whom I beg to acknowledge my indebtedness. He suffered little from reactive effects of the operation. At the end of the dal

first week there was very temporary tenderness of the thyreoid cartilage, painful deglutition, and discharge from the mouth of mucus tinged with blood. This condition, after an interval of comparative comfort, was followed by profuse muco-purulent discharge from the tube, renewed formation of granulation tissue, and gradual occlusion of the trachea. He was freely nourished, moved about his apartment, and maintained a resolute and cheerful condition of mind. At the end of the second week his strength had visibly failed, his lungs were passively congested, his respiration was becoming less sufficient, and he was delirious at night. On the day of his death he was unusually cheerful in the morning, ate his luncheon, smoked a cigar, and only began to suffer markedly from dyspnæa in the early evening. At eight o'clock, after two hours of delirious dyspnæa, he became unconscious. His breathing was afterward easy, and his pulse fairly strong, quite regular, and not more than a hundred in the minute. He remained eight hours in this condition without appreciable change, when he died somewhat suddenly on the seventeenth day after operation.

The tumor was very carefully examined by Dr. Gouley and by Dr. E. K. Dunham, of the Carnegie Laboratory, who concurred in the opinion that it was a commencing epithelioma. The sections made showed a stroma of fibrous tissue covered with stratified epithelium and containing nests of epithelial cells, many of which included "pearl bodies." From independent observations both gentlemen reached the conclusion that the process of degeneration had not extended over more than from three to four months.

If the direct influence of traumatism manifest in the preceding case of osteosarcoma, and possible in the earlier one of intraperitoneal sarcoma, is absent in the history of this case of epithelioma, it was still exerted in the formation of the original papilloma. There seems little doubt that an injury of the vocal cord sustained during a paroxym of coughing occasioned the benignant growth which later suffered degeneration.

The lengthened period during which this primary formation, though in continued process of growth and exposed to continued irritation, resisted its own inherent tendency to retrogression, to which it eventually succumbed, not only points the danger of the expectant, or rather drifting method of treatment, but is reassuring evidence that even in long-neglected cases a late operation, though in this instance it was unhappily a little too late, may yet chance to be in time.

It may be noted that the period during which degeneration is supposed to have begun embraces the time when the general health first distinctly failed. It is, of course, impossible to determine whether this coincidence has any significance, but it is a fact which naturally arrests attention.

The moral of these two later cases, as well as of the one which went before, seems to be the same: that safety only lies in the earliest possible removal of all tumors, whether benign or malignant. As all tumors, whatever their beginning, are liable to end in malignancy, and as the exact time when benign growths may be destined to transformation can not be predicted, so none can tell in how brief a time delay may become disastrous. If this moral seems trite to many members of this association, I beg them to remember that it is among the truths which still require reiteration,

for it is still far from universal acceptance as a guide in practice.

34 West Thirty-Seventh Street.

# TRAUMATIC ANEURYSM

OF THE DORSAL ARTERY OF THE RIGHT FOOT.

LIGATURE OF THE VESSEL, ABOVE AND BELOW THE TUMOR,

AND EXCISION OF THE SAC.\*

By JOHN W. S. GOULEY, M. D.

The rare occurrence of ancurysmal tumors in the dorsal region of the foot may warrant a record of the following case, which is interesting from this circumstance and from the method of treatment employed. The old operation of opening aneurysmal sacs, as revived, improved, and advocated by John Bell and later by James Syme, suggested to the writer the idea of excising as much of the sac as possible in this case after cutting off the circulation of blood in the parts by tying the artery above and below the sac. Two cases of aneurysm previously treated also induced the writer to open and excise the sac in this particular instance:

The first was the case of a private soldier who had received a sword thrust in the upper part of the left arm, and was brought to the writer, a few hours afterward, with a tumor the size of a hen's egg at the seat of injury. The external wound was small, and the skin had evidently been momentarily displaced so that afterward it acted as a valve to the tract leading to the artery. This and the blood coagulation in the adjacent connective tissue seem to have prevented grave hæmorrhage. Pressure on the subclavian artery having been applied, a free incision was made upon the tumor, which proved to be a firm clot of blood and was removed. The artery was then exposed and a ligature was applied above and another below a small oblique wound of this artery at the junction of its brachial and axillary regions, and the wounded part of the vessel excised. Thus a traumatic aneurysm in embryo was destroyed. The patient made a good and rapid recovery.

The second was the case of a man, twenty-two years of age. suffering from constitutional syphilis, who, two years before his admission to Bellevue Hospital on the 8th of October, 1871, had received a severe contusion in the right inguinal region, in consequence of which a large aneurysm had developed rapidly in the external iliac artery, and at the time of admission was already diffuse. It was decided to tie the primitive iliac, but all of the writer's colleagues voted against the proposition to open the aneurysmal sac. This artery was tied on the twelfth day of October and the tumor was left intact. On the sixth day after the operation a part of the sac could be seen through the unhealed lower half of the wound. This part of the sac, which was gangrenous, burst open on the tenth day, giving issue to decomposed blood. The patient died of pyemia on the nineteenth day, the ligature having been cast off. Had the sac been laid open during the operation, it is likely that the patient would have made a good recovery. The case is reported in the first volume of Transactions of the New York State Medical Association.

In his article on diffuse traumatic aneurysms, although John Bell expressed the soundest views respecting the

<sup>\*</sup> Read before the Society of Alumni of Bellevue Hospital, April 4, 1894.

progress and the management of these tumors, and although these views were advocated by other surgeons, they are not now carried into practice as often as they merit. His clear and precise language was substantially as follows: "When such an aneurysm holds, perhaps, not more than an ounce, it speedily increases until it contains ten or twelve ounces. The overlying tissues change, and the skin assumes a different hue and approaches sloughing. The sac itself becomes filled with coagula which perhaps plug the artery above and below. By this crowding and compression, sloughing occurs in the aneurysmal sac, and pyæmia is the consequence." To avoid this disastrous result he resorted to early incision of the aneurysmal sac, removal of the clots, and ligature of the artery above and below the open sac which he treated antiseptically, and sometimes at once excised. These experiences of Bell, Syme, and other eminent surgeons seem not only to justify but to demand the opening or even the excision of such aneurysmal sacs whenever they can be reached with safety. The writer's case of aneurysm of the dorsal artery of the foot is therefore reported as a small contribution to the statistics of this mode of procedure.

C. A. P., a carpenter, was admitted to Bellevue Hospital on the 19th of September, 1873. He had been in the habit of drinking spirituous liquors to excess for thirty years, but had had no serious constitutional disease. Thirteen years before his admission to the hospital he had received a severe bruise on the right instep from a falling stick of timber, and in consequence was lame for two or three weeks, after which he paid no attention to the foot until six months before admission to Bellevue Hospital, when he began to have pain in the instep which he attributed to a tight-fitting boot, and accordingly slit the boot at a point corresponding to the seat of pain. This relieved him for a short time, but he soon noticed a slight swelling of the instep, which increased slowly until three weeks before admission, and was not very painful. From that time to the date of his admission to Bellevue the swelling had doubled in size, had assumed a hemispherical form, two inches and a half in diameter, and had extended from the tibio-tarsal to the tarso-metatarsal articulations. The tumor was tense, elastic, and faintly pulsating in synchronism with the anterior tibial artery, the compression of which caused the interruption of a distinct bellows murmur and thrill discerned only a few moments before. It was, however, suggested that the tumor might be a highly vascular sarcoma by a colleague who thrust in an exploring needle, on whose withdrawal blood spurted as from an artery. The jet ceased as soon as pressure was made with a finger upon the anterior tibial artery, and the hæmorrhage was easily arrested by the application of a compress at the seat of puncture. This flow of blood so reduced the tenseness of the tumor that, when the artery was released from pressure, the pulsations became more distinct, and there was then no doubt of its aneurysmal nature. The skin on the outer aspect of the tumor was livid and tender. This and the sudden increase in its volume led to the belief that the aneurysm was already diffuse. It was therefore decided to tie the anterior tibial artery, to lay open the tumor, and to excise the greater part of its sac. On the third day of October the tibial artery was tied an inch and a half above the tumor, and another ligature was applied to the distal end of the dorsal artery of the foot. A free longitudinal incision was then made through the sac, clots of blood were removed from its cavity, and the

major part of this sac was dissected away, leaving only such portions thereof as were firmly adherent to the extensor tendons and to the tarsus. The wound was packed with lint saturated with a two-per-cent, solution of carbolic acid in glycerin, and a fenestrated gypsum splint applied to the leg and foot. The dressings were not disturbed until the fourth day, when suppuration was free, and parts of the sac which remained were sloughy and becoming loose. After this the wound was dressed daily.

On the seventh day a part of the extensor tendon of the great toe was found exposed and in a sloughy state, but the rest of the wound, except small portions of the sac, was covered with florid granulations. On the tenth day the remaining bits of the aneurysmal sac had been cast away, but the sloughy part of the long tendon was still held in position and was not removed until the next day. The distal ligature was cast off on the thirteenth day and the tibial on the twenty-third day. Owing to suppuration in the sheath of the long extensor tendon, an incision was made at the base of the great toe on the thirtieth day. From that time onward the process of cicatrization was uninterrupted. The wound was entirely bealed, and all dressings were removed on the forty-second day. The patient remained under observation thirty days longer. He was then able to walk well, and left the hospital in good physical condition.

It seems more than likely that in this case, if the operation had been delayed even a few days, the consequences of greater diffusion of the aneurysm would have been disastrous to the patient's foot if not to his life. This and other experiences surely point to the great importance of early radical surgical interference in diffuse aneurysms. Traumatic aneurysms of the dorsal artery of the foot were probably of frequent occurrence when venesection was as commonly performed in the foot as at the bend of the elbow by barber surgeons and itinerant charlatans in marketplaces, but are now rarely seen, and the traumatism is ordinarily of a different nature. Idiopathic aneurysms of this little artery are of such extreme rarity that many surgeons of extensive experience have never seen one. In 1874 the late Dr. S. D. Gross reported the first and only case he had ever observed of idiopathic aneurysm of a small artery of the dorsum of the foot, and this is the only case which has come to the writer's knowledge.

The laying open of aneurysmal sacs seems to have been recommended and practiced from the beginning of the last century. In the excellent bibliography appended to Erichsen's Observations on Aneurysm, 1844, the following instances are cited:

"In 1702, Saviard recorded a case of aneurysm at the bend of the arm caused by rupture of the brachial artery from a violent exertion. He laid the tumor open and then applied a ligature above and another below the opening in the artery." The same author gives "the history of a case of aneurysm occurring after bloodletting; in this he insists particularly upon the necessity of applying a ligature below as well as above the opening in the vessel."

"In 1712, Preuss reported a case of popliteal aneurysm, which being punctured and dressed with balsamic and styptic liquids, at length suppurated and was cured."

"In 1712, Klaunig, . . . an aneurysm of the external carotid from a sword wound, . . . when it burst, alum,

lint, and styptics were crammed into the sac; crysipelas of the face then came on, and the sac suppurating, the patient was cured."

"In 1716, Dionis... confines his observations to aneurysms at the bend of the arm, gives an account of their treatment by compression, and describes the operation of opening the sac; in which case he says that the hæmorrhage may be arrested in three ways: by compressing the ends of the vessel by means of paper pulp soaked in some styptic liquid, by a button of vitriol, or by ligature."

"In 1723, Garengeot . . . recommends compression and the ligature of the vessel above and below the tumor, which is then to be opened. . . ."

"In 1734, Teichmeyer and Emrich.... The aneurysm which occurred at the bend of the arm in consequence of a puncture of the brachial artery during bleeding was cured by being laid freely open."

"In 1769, Trew, . . . The aneurysmal tumor having been laid open, balls of paper pulp, soaked in spirits of wine, were tightly applied to the orifice of the artery . . . the patient was cured."

Doubtless many such other cases have been similarly treated.

The bold and successful treatment of an axillary aneurysm by incision, carried out by Syme in 1860 and published in Donald Maclean's edition of Syme's Surgery, is too well known to require more than its mention on this occasion.

# OZONE AND ITS USES IN MEDICINE.\*

BY WILLIAM J. MORTON, M. D.,

PROFESSOR OF DIMEASES OF THE MIND AND NERVOUS SYSTEM
AND OF ELECTROTHERAPEUTICS
IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

WRITING in the Asclepiad in 1890, Dr. W. B. Richardson, of London, the inventor of the ether spray for local anæsthesia, the introducer of peroxide of hydrogen into practical medicine, and in general a brilliant medical pioneer, said:

"In my essay describing the model city, Hygeiopolis, it was suggested that in every town there should be a building like a gas house in which ozone should be made and stored, and from which it should be dispensed to every street or house at pleasure. This suggestion was made as the final result of observations which had been going on since I first began to work at the subject in 1852.

"It occurred to me from the moment when I first made ozone by Schönbein's method that the value of it from a hygienic point of view was incalculable. To my then young and enthusiastic mind it seemed that in ozone we had a means of stopping all putrefaction, of destroying all causes which produce the great spreading diseases, and although increase of years and greater experience have toned down the enthusiasm, I still believe that one of the most useful fields for investigation remains almost unexplored."

Utopian as the general tenor of the above may have seemed at the time it was written, yet such is the rapid ad-

\* Read before the New York Academy of Medicine, June 1, 1893.

vance in electrical science, in chemical science, in bacteriology, and in the knowledge of the bactericidal properties of ozone, that in reality the day may not be far distant when Richardson's vision may easily mature into reality.

For, electrically, the ozonizer is no longer a plaything; it is a powerful instrument whose output is limited only by the limits of the horse power required to run the machinery which produces the ozone. This transition from an embryo to a mature stage is due to the growth of the induction coil or transformer, now capable of affording from five thousand to one hundred thousand volts, or possibly a million volts. Ozone, moreover, requires no rare chemical for its manufacture; it is merely ordinary oxygen of the air rendered active. With unlimited horse power and unlimited air or oxygen at command, ozone becomes, if desired, a commercial product capable of extensive use.

Chemically, also, progress is made which will work to make ozone available, for ozone has recently been compressed into a small volume and even liquefied. It liquefies about as easily as carbonic dioxide. By compressing a mixture of oxygen and ozone to one hundred and twenty-five atmospheres, Hautefeuille and Chappuis obtained gas in drops of a deep indigo color.

As a bactericide, ozone is coming no less favorably to the front.

Recently Ohlmüller and Fröhlich have killed, by means of it, the bacteria of anthrax, typhus, and cholera, as well as anthrax spores, and also the bacillus of pus; and lately I experimented upon the Staphylococcus pyogenes aureus, kindly furnished to me by Dr. W. H. Park, and after a few minutes' treatment by ozone the fluid turned from a milky color to limpid, and Dr. Park was unable to procure any cultivation from the treated fluid, showing that ozone really kills the pus germs, ordinarily so tenacious of life.

If, then, up to the present time—that is to say, within a year or two—many physicians and physiologists have held the opinion that ozone is not efficient to purify foul air, to disinfect clothing and dwellings, to sterilize drinking water, and in general to remedy unsanitary conditions, it is because the available apparatus produced but a small and practically valueless quantity of ozone and because the method of using it was little understood. Indeed, methods of its use are yet to be investigated.

For many years the writer has been familiar with the ozone produced in considerable quantities from influence electrical machines; has investigated and been astonished at its remarkable chemical properties; has made various attempts to employ these properties medicinally, and now finally, when the facilities are open to all for producing ozone on a large scale, has thought it would not prove uninteresting to collect some of the scattered data and present them as a whole to the members of the academy, adding some contributions of his own.

But undoubtedly the most important recent contribution toward investing ozone with properties of high value as a purifier of foul air and as a bactericide is contained in an article in a late issue of a report of the German Government (entitled Arbeiten aus dem kaiserlichen Gesundheitsante, vol. viii, first part, 1892), giving in detail the results of experiments made by Dr. Ohlmüller, of the Imperial Board of Health (Ueber die Einwirkung des Ozons auf Bakterien).

Dr. Ohlmüller in this paper refers to the labors of Wolffhügel (Ueber den sanitären Werth des atmosphärischen Ozons, Zeitschrift für Biologie, vol. xi). Wolffhügel's experiments confirmed Schönbein's opinion that the ozone in the atmosphere was a disinfecting agent, and that its varying quantities, as observed in dwelling rooms by different observers, were due to the presence in greater or smaller amount of organic impurities in the air. The correctness of this assumption was confirmed by experiment. One hundred and fifty-five litres of air taken from the open showed with the ozonoscope a coloration corresponding to Scale VI. The same quantity of air passed through a eudiometer, into which dust from the street had been blown, showed only a coloration corresponding to Scales III and IV. This dust incinerated with sodium lime gave a strong ammonia reaction. A sample of the dust thus treated was exposed to the action of two hundred and sixteen litres of air and showed with the eudiometer a coloration = V of the ozonoscope. A control experiment with another eudiometer, but without the dust, gave the same scale (V), demonstrating that the organic matter of the dust absorbed the ozone from the air.

Ohlmüller is of opinion that the reason of the many failures in the attempts to ozonize the air of sick-rooms is due to the comparatively small amount of ozone employed, and which consequently was insufficient to destroy the organic matter present.

He also takes the view that the cause of the failure of so many observers (Grossmann, Meyerhausen, Szpilmann, Fischer, Oberdörfer, Sonntagg, Oerum, Wyssokowitsch, Krukowitsch, Lukaschewitsch, and others), and the varying results obtained by them were due to the relatively small quantities of ozone they had at disposal for their experiments.

For this reason it was important to investigate under what conditions ozone acts on bacteria, especially as a favorable opportunity presented itself for obtaining ozone in unlimited quantity.

He found during his researches, under these more favorable conditions, that if the ozone and the bacteria be dry, no effect of the ozone on the bacteria was apparent.

With the bacteria dry and the ozone moist, typhus bacilli were destroyed in thirty minutes with forty-six litres of ozonized air = 289.8 milligrammes of ozone.

With ozone and bacteria both moist, typhus bacilli were destroyed in an hour, one hundred and eight litres of ozonized air being consumed.

His experiments with pus showed that after twenty-four hours with a consumption of two litres of ozonized air a minute = 11.5 milligrammes of ozone, the bacilli were killed (Staphylococcus pyogenes aureus), as was proved by inoculation of living subjects. Typhus, cholera, and anthrax bacilli placed in distilled and sterilized water were destroyed. Anthrax spores, after passing through water, 89.9 milligrammes of ozone; anthrax bacilli, 58 milligrammes of ozone; typhus and cholera bacilli, 19.5 and 16.5 milligrammes of ozone.

His experiments with sewage from the river Spree and water containing typhus and cholera bacilli demonstrated that the ozone had a destructive action.

He sums up by stating that the results of his experiments establish with certainty that ozone has a powerful destructive action on bacteria if the water containing them is not too strongly impregnated with lifeless organic matter (lebloser organischer Substanz). The result is the same when the lifeless organic matter is first oxidized to a certain degree by ozone.

In connection with cholera, now that ozone is known to be absorbed and again given up from fluids, we must note a valuable contribution, entitled Cholera; its Prevention and Treatment, by Elmer Lee, M. D., of Chicago, and Hydrogen Peroxide in Contagious Diseases, by Cyrus Edson, M. D., reprint from the *Doctor of Hygiene* for April last.

Both Dr. Lee and Dr. Edson (137) recommend free irrigation of the lower intestine as devised and recommended by Dr. Lee, and the free administration of peroxide of hydrogen, both by the stomach and by intestinal irrigation.

Dr. Edson says: "It is my opinion that this treatment will prove to be par excellence the treatment for cholera nostras, dysentery, typhus, and typhoid fever." As oil vehicles may carry as high as twenty-five volumes per cent. of ozone, it is obvious that they likewise may be effectually employed in the same diseases.

Fluid Vehicles for Ozone.—The Ozone Company have put upon the market several fluids containing ozone, giving to them the names aquozon, therapol, aerozol, kodozonol, and kreozonol. In spite of these unattractive names these liquids contain a large volume per cent. of ozone.

Ordinarily a hundred volumes of water will hold but half a volume per cent. of ozone, but by adding to the water about two per cent. and a half of hypophosphite of sodium it will hold about three volumes per cent. of ozone.

Aquozon, ozonized water, contains about three volumes per cent. of ozone.

Therapol, a bland vegetable oil ozonized, contains about eight volumes per cent. of ozone.

Aerozol, a combination of essential oils, the principal one of which is oil of spruce, contains twenty-five volumes per cent. of ozone.

Kodozonol is simply ozonized cod-liver oil; it contains about six volumes per cent.

Kreozonol is an ozonized oil of tar; it contains about ten volumes per cent. of ozone.

The volume percentage is determined by the amount of ozone set free by various reagents. The fact that aquozon, therapol, and aerozol contain ozone, and contain it in the percentages named, is established by the examination and report of Professor R. A. Witthaus. That oils absorb ozone in very large quantity and part with it slowly indeed requires no special corroboration, since it has been well known for a long time. The combination is not an oxidation, as one might expect, but the ozone is taken up by the oil as O's and yielded up as Os. In the aquozon preparation the hypophosphite of sodium is not oxidized

and converted into a phosphate, but it remains intact, and tests applied show the reactions of both the hypophosphite

Some of the writer's personal experiences and suggestions in regard to the therapeutic uses of ozone follow and may be of interest in advancing its employment.

His attention was first called to the therapeutic effects of ozone in 1884 when experimentally he caused a child suffering from severe chronic nasal catarrh to inhale the ozone produced by an influence machine. The acrid discharges, the falling back of secretions into the throat, the altered voice, and the continual sounds of attempts to clear the passages ceased after six inhalations. A sister of this child was also treated and cured.

Last fall, procuring a large machine from the Ozone Company, I made some further experiments as occasion The machine itself will be described farther on.

My first effort was to obviate the irritating properties of the ozonized air delivered from this or any large ma-

It is obvious that the electric effluvium, as it crosses the air space, will affect the nitrogen as well as the oxygen of the air. Thus not only is O, common oxygen, converted into O, or ozone, but also nitric acid and other noxious nitrogen compounds are formed. Accordingly, I used a wash bottle containing a solution of caustic soda or potash to pass the output of the machine through and to absorb the nitric acid. The ozone is now pure. This has added greatly to the respirability of the gas and obviated deleterious effects due to the nitrogen compounds. But even the washed gas if inhaled when too strong may irritate the bronchial mucous membrane and produce an asthmatic attack, with suffocative breathing, cough, and final mucous expectoration. As gutta percha is quickly destroyed, as well also other organic substances, I have had attached a goosenecked glass tube ending in a perforated cork. A variety of glass inhaling tubes may be attached to the cork; for the nose, simple straight tubes rounded at one end.

The preparations of ozone and the gas itself, when administered medically, part with their ozone within the human economy-just where, we would wish some one to determine. The most hopeful and general view is that the ozone increases the oxyhæmoglobin. This at least is conceded when ozone is taken into the lungs in gaseous form; the same may be true of the liquid preparations.

As it does not come within everybody's reach to own a large ozone machine, the importance of these preparations which hold ozone until it may be liberated within or upon some part of the patient is manifest.

The oil preparations give up their ozone when taken internally, and equally so when applied to external parts, as, for instance, to ulcers, diphtheritic membranes, and whereever a wound dressing is required. It is noted that these oils relieve pain more quickly than if they did not contain

Another improvement to the commercial machine was to have attached to it means for measuring its output in order to be able to express dosage in exact terms. This was effected by the aid of a meter to measure the amount of | of atrophic change, so familiar to all of you. In two the turbi-

oxygen or air passed through the ozonizing tubes and collecting the gas to estimate by reagents the number of milligrammes to a litre.

The following table exhibits the measurements of ozone in oxygen and in air produced by the generator of the Ozone Manufacturing Company's manufacture.

Ozonized oxygen, 1 litre a min.; quan. of ozone, 79-2 mgm. 2 litres " 135.6 mgm. 3 " 148.08 mgm. 4 " 168.0 mgm. 1 litre Ozonized air, 15.84 mgm. " (3 litres) 10 cub. ft. 45.84 mgm. " (6 litres) 2 10 . 6 70.0 mgm. i cubic foot = about 3 litres.

Nasal Catarrh.-Without making any especial effort to secure cases and purely as an experiment, I have treated a large number of nasal catarrhal affections by ozone, and have been surprised at the good results. Running the machine at a rate which produces about seventy milligrammes per minute of ozonized air, purified from nitric acid by the caustic soda, I cause the patient to blow and cleanse the nose as thoroughly as possible, to take a deep inspiration and hold the breath, allowing the ozonized air to be blown up one nostril and out at the other as long as the breath could be held; the patient is then instructed to blow the ozone gas out of the nostrils before inspiring, in order to avoid drawing the gas, in this strength irritating, into the lungs. This is repeated about six times to each nostril. The first feeling is one of intense dryness of the mucous membranes; then follows possibly a slight watery mucous discharge lasting for a few hours, and then next and subsequently the patient experiences great relief. This treatment was pursued thrice weekly, and five to ten treatments were sufficient to effect results. After treating ten cases successfully, and not caring to follow up nasal catarrh any further, I sent an eleventh case, a boy of twelve, who had suffered for two years, and who was so remarkably improved in five treatments as to attract much attention from his family, to my friend Dr. Clarence C. Rice to examine, with the suggestion to follow the matter up. The boy was a confirmed mouth-breather, his nose was thickened and red, his speech altered, and a continuous acrid discharge caused his upper lip to be constantly excoriated. He received ozone treatment two or three times weekly during about three weeks. The acrid discharge ceased, the lip healed, and he breathed well through the nose. Dr. Rice's examination confirmed these statements as to recovery and called attention to a rather marked adenoid enlargement in the vault of the pharynx. Following this case, Dr. Rice and I treated eight more cases on the indications and by the method above outlined. They were cases of atrophic rhinitis and dry pharynx. They all improved.

Delay in publishing this paper enables me to insert Dr. Rice's description of these cases, embodied in a communication read before the American Laryngological Association a few weeks after this paper was read at the New York Academy of Medicine:

"Three of my cases were advanced to an extreme condition

nates had almost entirely disappeared. The sæptum was ulcerated, and the secretions were collected in thick scabs. Of the two cases I sent to Dr. Morton's office, one was far advanced in atrophic change and the second was but moderate in degree. All of the cases were treated with the ozone gas from five to eight minutes. In Dr. Morton's cases the gas was passed into the nostrils three times-that is, while the patient was holding the breath for three different periods. The immediate effect of the ozone gas was alike in kind in all the cases, but differed in degree according to the volume of the gas employed, and probably according to the sensitiveness of the nostrils. It produced a mild smarting of the nasal mucous membrane for several hours. It increased the secretions of mucus very markedly for eight or ten hours. The congestion of the mucous membrane of the nose was also exaggerated. In some of the cases, where the volume of gas was large, the patients complained of headache, which, however, had disappeared by the following day. It was almost the universal testimony of these patients that the nasal pharyngeal mucous membrane was less dry, and that the tenacious secretions were more easily got rid of. For the first twenty-four hours after the ozone was used the patient had the symptoms of a cold in the head, but after that the nose felt unusually clear and the mucous membrane more comfortable than before the application of ozone.

"The milder cases of atrophic catarrh were very quickly benefited, and remained improved for several days after the inhaling of the ozone, but most of them relapsed somewhat. The benefit was again obtained, however, by the further treatment with ozone. Whether permanent moistening of the mucous membrane and decrease of secretions can be obtained by the use of ozone can be told only after a longer trial. In the more severe cases the benefit was not obtained so quickly. In all the cases we instructed the patient to discontinue the use of all sprays and douches while we were using the ozone. In a case of ozone seemed to be as marked as is obtained by the use of peroxide of hydrogen. The odor from the nostrils was very fettid, but disappeared altogether after the second inhalation of ozone gas." (New York Medical Journal). August 19, 1893.)

From further experience I am satisfied that results are equally good in hypertrophic catarrh, and also satisfied that a large volume of ozonized air—from 45 to 70 mgms, a minute—is essential to success in nasal cases. It is a great mistake to suppose that the mere smell of ozone will cure rhinitis.

Bronchitis.—Reducing the output of the machine to a point affording about one milligramme per minute, I have caused ozonized air, purified from nitric acid as before, to be inhaled in bronchitis, both acute and chronic, with great relief to the patients.

I cite but one case, since I simply intend my paper to be suggestive:

Case I. December 15, 1891.—Lieutenant F. P. F., aged thirty-six years. Between twenty and twenty-fire had several pulmonary bæmorrhages. Three years ago, after exposure in the Northwest, had a severe attack of what was carefully diagnosticated to be capillary bronchitis, lost forty pounds in weight in ten days, had severe cough, and other characteristic symptoms. Has had a persistent and severe cough ever since; sputa dark yellow, blood-flaked, and adhesive. Has severe and constant pain in the left side alongside the sternum on a level with the fourth rib. Had been treated variously and with no relief for the chronic bronchitis which had supervened upon

the cessation of the acute attack of capillary bronchitis. Physical examination revealed mainly the usual bronchial râles. He was treated four times—the 15th, the 19th, the 23d, and the 27th of December. The last entry in the note-book is: All the symptoms ceased; no cough at all.

Unfortunately for scientific accuracy, the treatment was by statical electricity as well as by ozone inhalations. Since the case is somewhat unique I read the patient's own letter written January 25th, about a month later. He says:

"Bedloe's Island, New York Harbor, January 25th.

"My DEAR DOCTOR: You have yourself to blame that you have not seen me lately, for since the last treatment I have not coughed once. I know that this reads like the remarks about patent medicines, where two bottles make the patients five years younger; but I never expected to be free from that infernal cough, and having to get up in the night and shut myself up in a closet to avoid waking the rest of the family up. When I catch a little cold now it goes off again and I never have the faintest pain in my chest. This is pretty good after three years of constant trouble that even the climate of California failed to in the least alleviate. I am coming up some day soon to show myself.

Sincerely yours, F. P. F."

Phthisis .- I will likewise offer but one case of phthisis:

Miss R., aged twenty-eight years. Referred to me by Dr. Frederick A. Burrall, of this city, with history of active pulmonary tuberculosis. Has had several attacks of hæmorrhage; has dullness under the right clavicle and dry pleurisy; has harassing cough, frequent slight hæmorrhages; can not retain her morning meal, and had reached a point where she was losing weight and her food was not assimilated. Duration of disease about two years. The noon temperature was usually about 99.5°; after treatment it was lowered to about 99°, though these relations varied from time to time. The patient received three treatments a week only. Since the third she has never failed to keep down her breakfast. She has received about twelve treatments and has gained six pounds in weight. Both statical electricity and ozone were administered. Her physician reports: "The cough has much diminished, the nausea quickly disappeared, patient has gained six pounds, and has evidently assimilated food and remedies. I notice the same improved pharyngeal hue from pale to ruddy which I noticed in the previous case [under the same treatment]. Her unfavorable symptoms are all generally ameliorated."

This was a year ago, and from reports received last summer I understand the patient retained the improvement gained.

Bactericidal.—Dr. William Hallock Park, of this city, connected with the laboratory of the Vanderbilt Clinic, College of Physicians and Surgeons, kindly consented to join me in some experiments upon killing bacteria. We have not yet completed these experiments, owing to unforeseen delays, but I submit a preliminary report from Dr. Park which is very satisfactory, so far as relates to the action of ozone when it is passed through fluids holding bacteria.

March 26, 1893.

DEAR DR. MORTON: The cultures made on the gelatin plates proved the preliminary report to be correct.

A summary of the experiments is as follows:

A considerable amount of a twenty-four-hours' growth on agar of the Staphylococcus pyogenes aureus was scraped off and suspended in five cubic centimetres of sterilized filtered Oroton water. 5 17

A culture of Klebs-Loeffler or diphtheria bacilli was treated in a similar way.

Small pieces of sterilized absorbent gauze were saturated with these cultures thus suspended in water and the pieces placed on a sterilized platinum wire net. This was placed in a wide tube through which a fifth of a cubic foot of ozonized air passed per minute. The bacteria were exposed different lengths of time—the staphylococi from five to thirty-five minutes, and the diphtheria bacilli fifteen to forty-five minutes. On removal the gauze was still moist.

Cultures of the staphylococci were made on agar and in gelatin. Those exposed for five minutes gave about as many colonies as the control, and those exposed the longest (thirty-five minutes) about half as many. The cultures of the Loeffler bacilli were made on solidified blood serum.

Those exposed fifteen minutes showed some diminution in the number of colonies on the cultures and those forty-five minutes still more, but still there were very abundant colonies.

The results showed that the staphylococci and the diphtheria bacilli when held on a moist piece of gauze are not greatly injured by exposure of thirty to forty-five minutes to a current of ozonized air.

The second experiment was to pass the ozonized air into the test tubes containing a watery suspension of the staphylococci. The air was passed into the mixture for five, ten, and fifteen minutes. The cloudy fluid was seen to quickly become clearer under the action of the ozone.

Cultures were absolutely sterile.

The result therefore showed that in the shortest trial (five minutes) all the staphylococci were killed by the action of the ozonized air dissolved by the fluid.

If you would like any fuller report let me know. I think it would be interesting to try some further experiments in passing the ozone into fluids. This part seemed very successful.

Very sincerely,

[Signed.] WILLIAM HALLOCK PARK.

Again, in the way of suggestion, I can see no good reason why gaseous ozonized air or oxygen may not be administered per rectum in cholera and typhus and typhoid fevers, just as in the familiar rectal gaseous administrations of sulphureted hydrogen for phthisis, though I am not aware that this method has been suggested or utilized in any disease.

There is another perhaps unimportant but novel point to which I may call attention. Taking, for example, iodide of potassium, free iodine is produced in its nascent state when ozone comes into contact with it.

Supposing that ulcerations, skin diseases, the nasal and throat cavities and other mucous surfaces and numerous conditions which will occur to all, be treated to a solution of iodide of potassium or any similar solution acted upon by ozone. The iodine or other liberated chemical acts in its nascent state upon the tissue.

In this manner the nose and throat might be first treated to a medicated spray and then to ozonized air, and the result be a new compound applied topically and nascently.

I have dwelt perhaps a little at length upon some of the therapeutic possibilities of ozone. There can be no doubt, it seems to me, that now that ozone may be generated on a large scale, its therapeutic properties should be tested on an equally large scale in hospitals, and definite knowledge

be obtained. More frequent and better opportunities present themselves in hospitals for testing the therapeutic value of ozone than are afforded in private practice. Ozone has too long been a sort of medical chimera; it is time that some one dispelled the illusions and laid bare the facts. One truth is clear—it is an oxidizing agency scarcely if at all inferior to nascent oxygen, while it possesses the advantage over nascent oxygen that it exists in gaseous form and may be disseminated as a gas into parts where nascent oxygen can not be utilized. Nascent oxygen can not purify the air of a hospital ward nor can it enter the lungs; its action is strictly localized to the very spot of its birth.

If we turn to the prophylactic and hygienic properties of ozone we must be struck with admiration.

Ozone attacks and renders innocuous organic matters such as smoke, sulphur compounds, and the great variety of organic matters which contaminate the air we breathe. Or, if we put it another way, these organic matters destroy or absorb ozone. Think of the quantity of ozone that would be destroyed in hospital wards, theaters, public halls, and schools.

Again, ozone sterilizes and purifies water; the most impure water can at once be rendered sweet-smelling, free from organic impurities, and free from pathogenic germs by passing ozone through it.

The purification of the water for drinking purposes of the river Spree is one of the prime objects of the investigations by the Imperial Board of Health of Germany, from whose report I have given some data.

It has been stated to me that our own Croton Water Board has appropriated a large sum of money to endeavor to secure the purification of Croton water by ozone. A gentleman interested stated that a first idea was to construct a great screen of platinum wire, through which the water should pass, while at the same time the screen formed an electrode to the current from great dynamo machines at work upon the banks of the river. One objection to this plan was that the sand would cut and wear away the wire—a matter of no small importance, since its value was estimated at twenty-eight thousand dollars.

In sufficient strength and quantity and in the presence of moisture ozone is, as I have abundantly shown, a disinfectant. When we recall the ever-latent danger of an invasion of cholera, and recall equally the exacting demands of a strict quarantine disinfection, we can not but feel that ozone, as now producible in quantity, may most properly form the subject of investigation on the part of our own board of health.

The problems which beset the utilization of ozone as a therapeutic agent are manifold—more difficult of solution perhaps than those which surround its introduction into the public uses outlined by Dr. Richardson in the opening sentence of this paper; but when experimentation and observation, more accurate and of wider scope than any now at command, shall be available, I have no doubt that ozone, like many another idea that has floated upon the medical horizon, will assume an important relation to the health of the individual and of the community.

(To be continued.)

# NOTE UPON PROFESSOR ANSCHÜTZ'S PURIFIED CHLOROFORM (SALICYLIDE CHLOROFORM).

By GEORGE RYERSON FOWLER, M. D.,

BROOKLYN, SURGEON TO ST. MARY'S HOSPITAL AND THE METHODIST EPISCOPAL HOSPITAL.

In this country the question as to the relative merits of ether and chloroform as anæsthetic agents seems to have been pretty generally settled in favor of the former. In Europe, however, the contention is still going on, particularly in Germany and France. In the former country chloroform still has the preference, and every effort is being made to improve the quality of the latter agent and the methods of administration thereof. In France ether is more or less employed, particularly in operations of long duration, as well as in weak children and old persons. At Kocher's clinic in Berne in the former class of cases the anæsthetization is commenced with chloroform, and when the process has been carried beyond the stage of excitement or that at which irritation of the air-passages occurs, ether is substituted. In Ollier's clinic at Lyons and in Jouillard's service in Geneva there has been an almost complete revulsion in favor of ether, the advantages attending its use being considered as far outweighing its inconveniences.

In spite of the fact that in this country ether is looked upon as the anæsthetic of choice, the expurgation of chloroform from surgical practice must be looked upon as very undesirable, to say the least. Practical surgeons, therefore, will always welcome every suggestion which will hold out the hope of eliminating the dangers incident to the employment of this agent, for with every care on the part of the administrator cases of fatal chloroform narcosis continue to be recorded.

It is more than probable that a certain proportion of these accidents are due to the use of an impure article; in addition to this, the technique of administration must govern, to a considerable extent, the measure of safety or of danger in individual cases.

Professor O. Weitzel, of Bonn,\* has recently brought forward a new chloroform for which the claim is made by Professor Anschütz, its originator, that by the employment of salicylic anhydride (C<sub>7</sub>H<sub>4</sub>O<sub>2</sub>), obtained by the action of phosphorus oxychloride on salicylic acid, forming what is known as salicylide, for purposes of purification, an absolutely pure chloroform results. By the action of the salicylide upon the chloroform a salicylized body is obtained in which the chloroform serves the same part as the water of crystallization in many salts, and consequently when heated the chloroform is separated in a pure state.

Professor Weitzel's experience with this product has been so favorable that I have been induced to import through Messrs. Lehn & Fink, of New York, a supply for trial. For the past month I have employed the preparation, and thus far have been exceedingly well pleased with the results.

The first point to be noted in connection with its use is the fact that, owing to the absence of that pungent

\* Centralblatt für Chirurgie, 1893, No. 52, p. 1151.

odor so commonly present in ordinary chloroform, there is a marked absence of hesitancy in the respiration and the occasional refusal to breathe observable in many cases where the latter is employed. The new preparation possesses a rather pleasant aromatic odor.

Whatever the cause, it is a well-known fact that in many persons, particularly those who have been in the habit of imbibing rather freely of alcoholic stimulants, even with the most careful administration of ordinary chloroform, there is a well-marked stage of excitement, this frequently amounting to violent struggling. Even in this class of cases this stage of the administration is only marked by an occasional exclamation when the salicylide chloroform is used.

The narcotic effect of the agent is obtained somewhat less rapidly than with common chloroform, and the patient must be carefully watched during the progress of the operation in order that he does not come out from under its influence. The first-named is not considered a disadvantage by skilled anæsthetizers, nor even the second, for the reason that so profound an effect is not obtained, the purposes of the anæsthetization are completely fulfilled, and the element of danger is largely eliminated. Complete anæsthesia can be brought about in ten minutes; a longer time is very exceptionally required.

Every surgeon of experience dreads the cases in which chloroform produces a very rapid and at the same time a profound narcotic effect. In fact, statistics of fatal chloroformization show that in the large majority of cases the dangerous symptoms supervened very shortly after the commencement of the administration. It is likewise true that the cases in which violent struggling takes place are also to be dreaded, and many surgeons refuse to permit of the continuance of the chloroform, substituting ether therefor, even when this has been apparently contraindicated, preferring to accept the chances of the supposed untoward effect of this agent upon atheromatous vessels, weakened respiratory organs, or diseased kidneys, rather than risk the occurrence of a catastrophe upon the operating table.

Next, the condition of the pulse is of importance in connection with the employment of the new chloroform. The heart's action, in no case under my observation, has been either accelerated or weakened by its use. On the contrary, when the pulse has been weak and excited prior to the administration, as frequently observed in nervous women, as soon as the effect of the salicylide chloroform has been obtained, a most pronounced improvement has been observed in this respect. A pallid face under these circumstances becomes of the pinkish hue of health, and remains so until long after the effects of the chloroform wear off, provided, of course, that excessive loss of blood, the prolonged manipulation of the abdominal contents, or other untoward circumstances incident to the operative procedure do not occur to produce the opposite effect.

Next, it is to be noted that patients recover consciousness much more promptly following the administration of Anschütz's chloroform than with the article heretofore in use. This occurs without those much-dreaded after-effects which are so marked a feature following anæs-

thetization with either chloroform or ether, as usually employed. In the case of an old man of seventy-four upon whom I operated for cerebellar abscess following middle-ear disease, in the practice of Dr. Zabriskie, of Glen Cove, the patient arose from the operating table and walked across an intervening parlor to his bedroom without apparent effort, within fifteen minutes after the withdrawal of the anæsthetic. This is not an exceptional experience, for it has been repeatedly noted that a marked absence of the usual head-symptoms, restlessness, muscular weakness, nausea, vomiting, and anorexia, is a pronounced feature of the use of this agent.

A word as to the method of administration: At the present day no surgeon of experience will permit his anæsthetizer to administer chloroform by any other than the drop method. The days of forcing the administration by pouring the chloroform in a stream upon the mask or folded napkin have gone by. Steadily supplying the chloroform drop by drop, keeping up by this means the administration of a small dose frequently repeated, produces the desired effect in a length of time sufficient for all practical purposes, and relieves the operating surgeon's mind of much anxiety in this respect. While I believe that chloroform purified by Professor Anschütz's process can be given with somewhat greater freedom without the risks incident to rapid administration of common chloroform, yet I have up to the present time refrained from pursuing a course in this respect other than that which I would follow in the use of the latter. In other words, I have followed the drop-by-drop method with the head lowered, precisely as I would in ordinary chloroformization.

The quantity of the new chloroform required, even in the hands of those not skilled in its use, averages about one cubic centimetre for each three minutes of complete narcosis. In case the anæsthetizer is accustomed to its use, and keeps the patient just evenly balanced between unnecessarily deep narcosis and the beginning of the return of consciousness, a smaller quantity will suffice.

It is furnished by the manufacturers \* in brown-colored graduated bottles containing fifty grammes each, a quantity sufficient for the purposes of an average operation. An exceedingly simple dropper device is furnished with each bottle.

# THE OXYTOCIC ACTION OF SALICYLIC ACID AND ITS COMPOUND WITH SODIUM.

By HIRAM N. VINEBERG, M. D.

The salicylates are so frequently administered that it is well to be familiar with all their actions and effects. There is one property they possess which I believe is not generally known. On looking up the works on therapeutics that I possess (Ringer, Wood, Bartholow, Edes) I find no mention of the action of the salicylates on the genital organs of women. This is very strange, for they certainly do have a very marked influence as an oxytocic and emmenagogue. B. Schuchardt † drew attention to the fact

that under the administration of salicylates the menses became more profuse and lasted longer. He observed also four cases of abortion which he attributed to the remedy used for another purpose. Quite recently C. Binz \* has written a paper upon the action of salicylic acid on the uterus. He experimented upon eighteen guinea-pigs, and of these eight aborted as a result of the administration of the drug. But the dose was so large in three of these as to cause toxic symptoms; hence, they must be excluded. In the other five, however, there seems no doubt, in my mind, as to the abortion being directly due to the drug.

Within the past few months I have observed two cases in which the administration of salicylate of sodium seemed to have a decided effect upon the uterus.

In the one case the woman was seized with acute articular rheumatism on the fourteenth day after a normal confinement. The labor and puerperium were normal in every respect. The lochia had been normal and before the rheumatism had set in they were scanty in amount and grayish-yellow in color. Salicylate of sodium was given in fifteen-grain doses every three hours, and as the attack of rheumatism was very severe the remedy for a few days was given every two hours. On the second day of its administration the patient had quite a severe uterine hæmorrhage, although bimanual examination of the uterus showed that involution had progressed normally. During the three weeks that the drug was administered the woman had more or less uterine hæmorrhage most of the time, and it ceased only when the salicylate was discontinued.

Involution of the uterus, however, seems not to have been interfered with, for at the end of six weeks the uterus was about the size of a fully involuted uterus and was only a slight degree larger than the healthy nonparous organ.

The second case occurred in a young, delicate girl of eighteen, who had been under my care for some time for scanty and delayed menstruation and for general debility. She had always been delicate and her development in general seemed to be below the normal standard. My treatment, therefore, was directed to her general condition, leaving the uterine function to take care of itself. Recently she had an attack of acute amygdalitis, for which her physician prescribed fifteen grains of salicylate of sodium every three hours. She and her mother were surprised to find that menstruation had set in on the second day of the illness and fully a week sooner than it had ever occurred before. It was also decidedly more profuse than it had ever been. She suffered from "cramps" with the onset of the flow, but not any more than usual.

As a result of my own observations in the foregoing cases and also in others, and from a perusal of the literature on the subject, the following conclusions seem warranted:

- Salicylic acid and its compounds may be found useful in scanty and delayed menstruation.
- They should not be administered to pregnant women who have a predisposition to abort or who suffer from menorrhagia and metrorrhagia.
- 3. Their administration should be watched carefully in all cases of pregnancy, and on the appearance of any "show," or anything resembling labor pains, they should be discontinued.

THE

# NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co. Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 23, 1894.

# THE ELASTICITY OF THE BRAIN.

In No. 333 of the Proceedings of the Royal Society there is an account, communicated by Mr. Horsley, of an investigation, by A. G. Levy, M. B., of London, entitled A Research into the Elasticity of the Living Brain and the Conditions Governing the Recovery of the Brain after Compression for Short Periods. The investigation was conducted in the laboratory of the pathological department of the University College, and the British Medical Association, at the recommendation of its scientific grants committee, contributed toward the expense attendant upon it. The author remarks that, in view of the great frequency of compression of the brain as a pathological condition, it had seemed very advisable to attempt to obtain some knowledge of the elementary factors governing the physical changes in the brain substance due to mechanical pressure. Reference is made to an article by Grashey, Ueber Hirndruck und Hirncompression, published in the Allgemeine Zeitschrift für Psychiatrie, vol. xliii, in which, it is remarked, proof was shown that the coefficient of compressibility of the dead brain was slightly less than that of water-in other words, that under any ordinary pathological condition the brain tissue was incompressible. The author says that his attempt to determine the elasticity of the living brain-i. e., of the brain mass including its full complement of circulating blood and lymphand further to test the truth of the generally accepted view that the elasticity of the brain was proportional to the blood pressure, was undertaken at the suggestion of Professor Horsley, who devised an apparatus for the purpose and aided the author with advice and suggestions.

The brain was experimented upon in situ, the influence of the cerebro-spinal fluid being excluded by the mere fact of the skull having been opened and the membranes partially reflected, thus freeing the fluid from all tension. In the first place, there were considered the results of experiments performed upon freshly exposed brains, the blood pressure being at its normal height, in order to arrive at some conclusion as to the normal elasticity of the brain. The downward movement of a plunger was measured after a given interval of time, and the extent of this movement was termed the "excursion." The recovery of the brain surface, to the extent of which the term "recoil" was applied, was measured until its further development ceased to be perceptible. The general character of the "excursion" was found to be that of a rapid plunge downward taking place within the space of one or two seconds, followed by a much more gradual compression. Its extent varied within a considerable range in different animals; thus, a weight of fifty grammes applied for a minute produced an "ex-

eursion" which varied in different dogs from 4.5 to 7.3 millimetres. It also varied notably with the weight employed. There was no obvious relation between the depth of the "excursion" and the blood pressure. For convenience of expression and for the purpose of comparison, the ratio of the "excursion" to the "recoil" was expressed in the full paper in the form of a fraction, and this ratio was termed the "proportionate recoil." The smaller this fraction the feebler was the elastic reaction it denoted, and vice versa. The comparison of the ratios derived from experiments performed under like conditions upon different animals brought out the striking approximation which they bore to each other, whatever the length of the "excursion" or whatever the existing blood pressure might be. Such deviations from the average as the ratios presented could not be found, moreover, to have any relation to variations in either "excursion" or blood pressure. Compression by a fifty-gramme weight for a period of from thirty to sixty seconds yielded an average "proportionate recoil" of one half. A further comparison showed definitely that the longer was the period of compression the less was the "recoil"; thus, with a compression of only two seconds the reaction was sometimes almost perfect, whereas compression lasting six minutes yielded a ratio of one divided by 2.74. In like manner heavier weights damaged the brain in a way prejudicial to its recovery.

A series of experiments were performed with a view to comparing the elasticity of the brain at the normal blood pressure with the elasticity of the same brain at an artificially lowered blood pressure. The first method employed was that of producing a large fall of blood pressure by bleeding. The results tended to confirm the impression that there was no constant relation between brain elasticity and blood pressure. The experiments of this series were somewhat vitiated by the partial collapse of the cerebrum which ensued during the process of bleeding, so a second series was instituted in which the blood pressure was lowered under the action of amyl nitrite; the brain, becoming flushed with blood at the moment of the administration of the drug, had no tendency to collapse. Under the influence of the nitrite the cerebral vascular conditions were such that the elasticity was actually increased, thus conclusively demonstrating that the latter did not depend upon the central arterial pressure.

Further experiments were performed in view of the influence believed to be exerted by venous pressure upon the cerebral circulation. The accessible cranial veins were exposed and clamped in succession, and the variation in the intracranial pressure thus induced was measured. The results tended to show that the increase of intracranial pressure must be considerable to influence the elasticity in even a small degree. Experiments performed upon brains which had undergone prolonged or severe compression showed that a considerable increase of arterial blood pressure was quite unable to restore the volume of a brain thus damaged, whereas an increase of venous pressure obtained by asphyxiation brought about this restoration rapidly and usually completely.

### HYSTERICAL APOPLEXY.

AT a meeting of the Paris Société médicale des hopitaux held on the 25th of May M. Comby, according to the account published in the Mercredi médical for May 30th, remarked that hysterical apoplexy had been well known since the cases that been reported to the society by M. Dubove and M. Dumontpallier, since the appearance of M. Achard's thesis, in 1887, and since the publication of the works of Charcot and his pupils, There was, therefore, nothing surprising about the case which he would speak of, but it had appeared to him interesting by reason of the ætiological conditions that had given rise to it and by the evolution which it had presented. On the 20th of April a woman, thirty-eight years old, had entered the Tenon Hospital for left hemiplegia, with which she had suddenly been attacked on the day before. She had had a previous attack in 1889, under the following conditions: During a thunderstorm two of her children were struck dead at her side with lightning, and she herself was rendered unconscious. When she came to herself it was perceived that she had complete motor and sensory paralysis of the left side. The hemiplegia disappeared in three weeks. In July, 1891, two years after the first attack, the patient was again seized with apoplexy on a stormy day. On the 9th of April, 1894, the day preceding her entrance into the hospital, her trouble had once more been renewed during heavy or tempestuous weather. Her condition was that of apoplexy, followed by left hemiplegia. An objective examination revealed the existence of complete paralysis with hemianæsthesia, and the diagnosis could only be that the affection was of an hysterical nature. The case was presented as a very striking example of recurrent hysterical apoplexy.

M. Comby remarked that this trouble was not rare, for at that time there were in his service two other patients who had been seized with hysterical apoplexy under analogous conditions. One of them was a woman who, on seeing her child set fire to some fabrics in her chamber, had fallen unconscious and awakened some time after with left hemiplegia accompanied with anæsthesia. At the time of the report the power of motion had returned, but the anæsthesia persisted. The other case was that of a man, somewhat given to alcohol, who, five days before, in consequence of a very disturbing occurrence, had suddenly been stricken with apoplexy, and there was still left hemiplegia with complete anæsthesia. M. Comby added that it was well to bring such cases to notice, to aid in guarding against errors of prognosis.

# MINOR PARAGRAPHS.

### THE MEDICAL SCHOOL OF COLUMBIA COLLEGE.

It is announced that, beginning with the academic year 1894 to 1895, the work required of students who are candidates for the degree of M. D. will cover four years of study according to the curriculum set forth. This extension of the course does not affect students who have already matriculated and attended a session. The first year's course includes physics and chemistry, with medical chemistry; anatomy; normal histology; and

physiology. The second year's course includes anatomy; normal histology; physiology; pathological anatomy; bacteriology; materia medica and therapeutics; toxicology; and obstetries and gynæcology. The third year's course includes materia medica and therapeutics; pathological anatomy; pathological histology; the practice of medicine, including the diseases of the mind and nervous system; the principles and practice of surgery; obstetrics and gynæcology; venereal diseases; diseases of the eye; and diseases of the ear. The fourth year's course includes the practice of medicine, with the diseases of the mind and nervous system; clinical microscopy; the principles and practice of surgery; orthopædic surgery; obstetrics and gynæcology; diseases of children; diseases of the skin; and diseases of the throat and nose. Fourth-year students will be required to choose one or more from a list of elective courses of which the following are proposed: Surgical diagnosis; obstetrics; the diagnosis of nervous diseases; the localization of nervous diseases; insanity (a clinical course); ophthalmology; venereal diseases; the therapeutics of diseases of the skin; contagious diseases; microscopical technology; the pathological anatomy and histology of the organs of generation; the pathological anatomy and histology of the nervous system; cellular biology; comparative embryology; human and comparative morphology; neuro-muscular physiology; physiological technique; physiological and experimental psychology; philosophy; botany; chemistry; and physics.

# THE SANCTITY OF THE HYMEN.

Dr. E. S. McKee, of Cincinnati, is engaged in the laudable endeavor to impress upon his professional brethren the importance of preserving the hymen. In a reprint from a work by Dr. A. Martin, of Berlin, he adds to the melancholy

> So Mancher suchte sie im Dunkeln, Und fand statt ibrer nur Karunkeln

this further couplet:

Magnum est crimen
Perrumpere virginis hymen.

#### A LIKELY STORY!

Every now and then something is printed in one of the newspapers that may well lead to doubt as to whether any sort of attempt is made by them to distinguish between what is within the bounds of probability and what is palpably and grotesquely incredible. For example, one of the morning papers lately printed a dispatch from Chicago announcing that some doctor of that city had been "commanded" by the German Emperor to visit the military hospitals of the empire for the purpose of instructing our German colleagues in the cure of certain diseases. It was added that this individual would receive the highest military honors in Germany, and that he would be escorted in state from the frontier to Berlin by a detachment of the Imperial Guard!

#### ITEMS, ETC.

The Cleveland Medical Society held its second quarterly meeting on Friday evening, the 22d inst. The programme included an address on The National and Municipal Relations of the Medical Profession, by Dr. William Pepper, of Philadelphia; and remarks on Leprosy in Spain and Morocco and Medicine among the Moors, by Dr. William T. Corlett.

Syracuse University.—The twentieth annual meeting of the Syracuse and Geneva Alumni Association of Syracuse Medical College was held in Syracuse on Thursday, the 14th inst. An address was delivered by Dr. A. F. Vandebon-

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 19, 1894:

DISEASES.	Week ending June 12.		Week ending June 19.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	5	2	6	1
Scarlet fever		14	114	17
Cerebro-spinal meningitis	1	1	4	4
Measles		5	131	12
Diphtheria	208	43	244	60
Small-pox		3	15	3
Tuberculosis	145	135	108	84

The Berlin Obstetrical and Gynæcological Society.—At a meeting of the Gesellschaft für Geburtshilfe und Gynākologie held on April 13th, a report of which is published in the Centralblatt für Gynākologie for May 26th, Dr. T. Gaillard Thomas and Dr. Thomas Addis Emmet, of New York, and Dr. Theophilus Parvin, of Philadelphia, were nominated as honorary members.

Yale University.—The annual address in medicine, on The Illustrious Boerhaave, will be delivered by Dr. William T. Lusk, of New York, on Tuesday, the 26th inst. In the evening the faculty will give a reception in honor of Dr. Lusk at Dr. William H. Carmalt's house.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 10 to June 16, 1894:

Gibson, Joseph R., Major and Surgeon, Fort Snelling, is granted leave of absence for one month on surgeon's certificate of disability, with permission to apply to the proper authority for an extension of three months.

HOWARD, DEANE C., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Buford, North Dakota, and will report in person to the commanding officer, Fort Snelling, Minn., for duty at that station.

# Promotions.

Wales, Philip G., and Ten Eyok, Benjamin L., First Lieutenants and Assistant Surgeons, to be Assistant Surgeons, with the rank of Captain, June 7, 1894, after five years' service, in conformity with the act of June 23, 1874.

# Society Meetings for the Coming Week:

Monday, June 25th: Medical Society of the County of New York; Boston Society for Medical Improvement; Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, June 26th: Buffalo Obstetrical Society; Medical Societies of the Counties of Essex (annual—Elizabethtown) and Lewis (annual), N. Y.

Wednesday, June 27th: New York Pathological Society; Metropolitan Medical Society, New York (private); Medical Society of the County of Albany, N. Y.; Auburn, N. Y., City Medical Association; Berkshire, Mass., Medical Society (Pittsfield); Philadelphia County Medical Society.

THURSDAY, June 28th: Medical Society of the State of New Jersey (first day—Lake Hopatcong); New York Academy of Medicine (Section in Obstetrics and Gynæcology); New York Orthopædic Society.

FRIDAY, June 29th: Medical Society of the State of New Jersey (second day).

# Wetters to the Editor.

THE CRAZE FOR PHOTOGRAPHY IN MEDICAL ILLUSTRATION.

GALVESTON, TEXAS, June 15, 1894.

To the Editor of the New York Medical Journal:

Sir: The letter of "Medicus" and your leader on this topic in your issue of June 9th were well timed. Undoubtedly some modern works and many articles on gynæcology are illustrated by photographs which expose the person quite unnecessarily, and therefore indecently, and which coming before the eyes of the laity are not calculated to raise the public estimation of professional delicacy. Especially objectionable are the photographs of nude women in innumerable modifications of the dorsal, dorso-lateral, and Trendelenburg positions which have lately become fashionable. These photographs teach nothing that could not be equally well or better taught by a good diagram; nor is it possible to demonstrate the necessity of the absolute lack of drapery and reproduction of the model's features. Let us have no prudery in medicine or in our daily life, but let us also be doubly circumspect lest we err on the other side.

But there is another view of the matter hinted at in your leader which writers, editors, and publishers would do well to consider carefully. The excellence and cheapness of the recent methods of reproducing photographs by photo-engravings has driven the majority of medical illustrators photo-mad. How many text-books and articles are spoiled by beautiful photo-engravings which teach absolutely nothing, where simple diagrams would have been most instructive!

Take, first, the whole series of photographs of microscopic slides. What is to be learned from any one of them compared with a careful line engraving or water-color sketch of the same object? Who has not been profoundly disappointed with his own results, which he has nevertheless published. There is not one per cent. of the micro-photographs published that are intelligible to any one except the possessor of slide and photograph who can carefully compare the two. Yet a very little training of our laboratory students in histology will enable a considerable proportion of them to produce a diagram quite intelligible to any one accustomed to microscopic work.

Passing to the naked-eye specimen, how often is the very point of most importance in the illustration completely obscured by the photograph!

The possessor of specimen and photograph is not a fair judge. It is comparatively easy, after comparing the two, to make out the points in the photograph, when the latter may be quite unintelligible to the reader. How many published photographs teach us nothing except that the surgeon had a specimen and photographed it! It was round, or oval, or irregular, and covered by adhesions. We could have believed all that without seeing the photograph. But it is not the multiplicity of photographs that we are suffering from; we can look at them or not as we prefer; but they are depriving us of diagrams-that might have taught us something. Of all photographs the anatomical one is most disappointing. There is no anatomical point that can not be illustrated efficiently by the simplest diagram, and no amount of photography will enable a man without

a practical anatomical training acquired by his own scalpel in the dissecting room to appreciate any anatomical point whatever.

I have no hesitation in saying that the diagrams in Gray's Anatomy teach more than the elaborate engravings in Morris's Anatomy of museum specimens of dissection in London, and had these engravings been photographs they would have taught nothing at all. Even an artistically correct engraving often fails in showing too much and neglecting to emphasize what is important. Those who have employed artists to paint their specimens know how closely they must be watched by the educated eye; and every medical artist knows how artistic effect must be sacrificed to scientific accuracy or even to that little touch of exaggeration or diagrammatic simplification which is constantly necessary to make the drawing tell its story.

That there is a most important field for photography in medicine no one will deny; that medical photographs are, in nine cases out of ten, almost entire failures or teach ever so much less than a simple diagram would have taught, every one will admit. Let us, then, endeavor to give it its due place; to employ the photograph, the simple diagram, or the careful drawing in colors, or black and white, as each shall best illustrate the matter in hand. If the teachers of every large medical institution would club their work together so that they might employ a young physician with a thorough art training (a physician that he might understand what he was expected to reproduce, an artist that he might be able to represent what was visible to his educated eye), a new post might be created which would be a valuable prize to talent in each such teaching center, and our books and magazines would be enriched with much benefit to the world of medical readers.

WILLIAM KEILLER, M. D.

### THE MATTER OF GONORRHEA INSONTIUM.

RED LODGE, MONT., June 7, 1894.

To the Editor of the New York Medical Journal:

Sir: Dr. A. Lapthorn Smith's letter in your issue of June 2d, on Gonorrhæa without Coitus, recalled an unusual case of gonorrhæa which I had recently discharged, and an account of which I thought might be interesting.

I was called to see a little boy twelve years of age, with whose penis something was wrong. Upon examining that organ, I found a condition resembling paraphimosis. The prepuce was drawn back over the glans and was very much swelled. The skin of the prepuce was stretched to such a degree that it was almost transparent. The child told me that his prepuce was not naturally tight, and that it usually slipped backward and forward over the glans without any difficulty. I could not replace the foreskin in its natural position, and, as the glans did not seem to be much constricted, I did not try very hard to replace it. Among other things I noticed a drop of pus at the orifice of the urethra, and the patient said the act of urinating had been very painful for several days, although there had been no pus till the day on which I saw him.

Sending all the other members of the family out of the room, I questioned the boy closely as to what he had been doing. He seemed to be such a child, being-even smaller than bis age would indicate, that I did not persevere very long in trying to get him to confess that he had been indulging in sexual intercourse, yet I commenced treating him for gonorrhea. I did not tell the parents what my diagnosis was, but as they were frightened, I had no difficulty in keeping the boy in bed.

Of course no injections were used at this stage, yet in a few days the boy had typical orchitis in the left testicle. Evasion of

the parents' questions was becoming difficult, yet I knew they would not believe my diagnosis to be correct, unless I could get a further confession from the boy. Again I sent every one except the patient out of the sick-room, and, putting my questions into words which every boy can understand, I asked him if he had ever had sexual intercourse with any one. He assured me that he never had. I then assured him that I knew he was lying, and that he might as well tell me the truth, whereupon he confessed that he had had intercourse with a little schoolmate about ten years old. Upon further questioning, I learned that he had been carrying on a liaison not only with this little girl, but also with another of about the same age. He repeatedly denied having had anything to do with any one else, which denials I did not believe; but I had learned enough, and I gave the parents my diagnosis, which, under the circumstances, they did not question.

The boy made a prompt recovery, but this case taught me that a person is extremely young who is too young and too innocent to acquire gonorrhea in "the good old way."

A. C. McClanahan, M. D.

#### AN IMPOSTOR.

ALBANY, N. Y., June 13, 1894.

To the Editor of the New York Medical Journal:

Sir: During the last fortnight I have received inquiries from physicians in Lambertville, Keyport, and Perth Amboy, N. J., concerning a young man who has lost his left hand and professes to have been a student in the Albany Medical College. He gives the name of George, with different given names in different places, and is soliciting aid from physicians and druggists under various pretexts. I am informed that he exhibits a letter of recommendation purporting to have been given him by me, and I beg to say that I know of no such man and that we have never had a student answering to his description. By publishing this note you may prevent physicians from being further imposed upon.

\*\*Registrar\*, Albany Medical College, Medical College, 1985.

# Proceedings of Societies.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Third Triennial Meeting, held in Washington on Tuesday, Wednesday, Thursday, and Friday, May 29, 30, and 31, and June 1, 1894.

The President, Dr. Alfred L. Loomis, of New York, in the Chair.

(Concluded from page 758.)

The Surgery of the Accessory Sinuses.—In the first part of the fourth day's session, under the direction of the American Laryngological Association, this was the subject for discussion.

Ethmoidal Disease.—Dr. F. H. Bosworh, of New York, opened the discussion with remarks upon this aspect of it. He said that when dealing with disease in the ethmoidal cells, especially where suppuration had occurred, an opening into each of the large number of small cells was requisite; but, as this was practically impossible, the treatment should consist in breaking down these cells into one large cavity. Ethmoidal

disease was the cause of a train of symptoms, such as a watery discharge from the nose, sneezing, neuralgia, asthenopia, and a peculiar condition in which the patient found it impossible to fix his mind on any subject. A very large proportion of cases of supposed acute rhinitis were probably instances of ethmoidal Rhinoscopic examination during the inflammatory disease. stage of the disease would show the middle turbinated body as a rounded mass encroaching upon the middle meatus of the nose. The ethmoidal cells he considered to be part and parcel of the turbinated body. As a general rule, where there was chronic inflammation of a mucous membrane within a closed cavity, the tendency was to abscess formation. A "dropping in the throat" should suggest the possibility of an empyema of the sphenoidal or ethmoidal cells. He did not attach much importance to the use of the probe in diagnosis; he depended chiefly on the appearances observed about the middle turbinated body. He favored the use of the Thudichum douche, one or two gallons of very hot saline water being passed through the nasal cavity at least twice daily. There was no danger of exciting ear trouble by this treatment if the patency of each nostril was tested previously, and if the stream of water was made to enter through whichever naris was found narrowed. After the occurrence of suppuration, the cells should be uncapped by means of a snare, and then with the dental burr they should be broken down into one large cavity. It was often necessary to repeat the operation many times.

The Surgery of the Maxillary Sinuses .- Dr. J. H. BRYAN, of Washington, continuing the discussion, said that empyema of the maxillary sinus had formerly been considered to be a condition of rare occurrence, but it was now known to be more frequent. Cysts and other tumors of the antrum had been included in the older descriptions of empyema of this cavity. If there was a carious tooth, and there usually was, it should be extracted. If the cavity was not opened by this method, communication would have to be established by means of a small trephine propelled by a motor. The cavity should be perforated at its most dependent part, and the opening made sufficiently large to admit of the passage of a small metallic drainage-tube. In this way excellent drainage would be secured, and the method allowed of the patient's carrying out a large part of the subsequent local treatment. The objections were that a sound tooth might have to be extracted, and that pathogenic germs or food might pass from the mouth into the cavity, and so infect it. If it was desirable to open the cavity through the nose, then some modification of the Mikulicz method should be adopted. After opening the cavity, it should be frequently washed out with a mild antiseptic solution, and an effort should be made to fill the cavity to its greatest capacity. The simpler and less irritating the application, the more readily would the secretion subside. By an adaptation of the endoscope the speaker had been able to inspect the cavity. Such an examination would often reveal polypi, supernumerary teeth, or necrosed bone as causes of the long persistence of the symptoms.

Benign tumors of the maxillary sinus were usually cysts, polypi, osteomata, or fibromata. Among the malignant growths found here were epithelioma, carcinoma, and sarcoma.

Dr. J. N. Mackenzie, of Baltimore, said that the interest of this discussion centered upon the manner of reaching the interior cavity. There were several ways of opening the antrum, as had been described by the last speaker. Not only was the natural opening to the antrum difficult of access, and the operation painful in spite of the use of cocaine, but the subsequent syringing, which often required to be continued for many months, was disagreeable and painful. It had been proposed to remove the middle turbinated bone as a preliminary step, but

this procedure did not seem justifiable so long as other methods were at our disposal. An opening might be made through the inferior meatus just below the normal opening, but it was sometimes attended with quite free hæmorrhage, and the antrum was occasionally so thick at this point that it was impossible to penetrate it with the spear-shaped knife of Mikulicz. He would add that this knife was not so suitable for the operation in any case as the drill. An opening into the antrum through the canine fossa should be attempted only where there were growths in the antrum or where the walls of the antrum were unusually thin. The best way of gaining entrance into the antrum was through a tooth, and the great advantage of this method was that it secured absolutely perfect drainage, while affording a counter-point of drainage through the nose. The tube could easily be plugged if one feared the entrance of food into the cavity, but as a matter of fact food did not generally gain access to the cavity.

Dr. John O. Roe, of Rochester, divided disease of the accessory sinuses into acute and chronic. The chronic form included empyema, mucocele, and other growths. The acute diseases rarely required surgical interference. Empyema of these cavities should be looked upon rather as a symptom than a disease. The successful treatment depended on a correct understanding of the seat of the disease and of its pathology. If the disease was not of long standing, he would usually begin treatment by injections through the natural passage. When catheterism was impossible, an artificial opening should be made through the socket of a carious tooth or, if the tooth was sound, through the zygoma.

The Influence of Infectious Processes on the Nervous System was discussed during the remainder of this session, which was under the direction of the American Neurological Association.

Dr. James J. Putnam, of Boston, discussed the pathology and ætiology. The infectious diseases generally admitted ascauses of nervous affections were tetanus, rabies, syphilis, tuberculosis, hysteria, lepra, gonorrhœa, typhoid fever, erysipelas, influenza, mumps, the acute exanthemata, the presence of pyogenic organisms or of the Diplococcus lanceolatus, malarial disease, and actinomycosis. The nervous troubles following acute infectious disease were not always due to the primary infection. but sometimes to a secondary infection; or they might be only an indirect result. The more important diseases of the nervous system which had only been suspected of being of infectious origin were poliomyelitis, Landry's disease, certain forms of myositis, neuritis, and myelitis, some of the cerebral palsies of children, chorea, disseminated selerosis, and other cerebro-spinal scleroses, amputation neuritis, and herpes zoster. Finally, there were various affections following in the wake of infectious processes, but hardly to be classed as indicating the action of a specific virus. Such were the constitutional neuroses and psychoses and the advnamic cerebral affections, the result of œdema or of arterio-sclerosis; various forms of sclerosis of the spinal cord, to which the nervous system was always prone; and subacute forms of multiple neuritis of the ordinary type.

The argnments were strong in favor of the infectious origin of the different forms of the acute myeloneuritis or poliomyositis, which appeared to be due to powerful poisons acting like bacterial toxines. Bacteria had been found in Landry's disease, and myelitis had been produced experimentally by infection with cultures. Acute multiple neuritis might follow almost any one of the infectious processes. The meningitis which followed the exanthemata was probably due to secondary infection. The specific organisms prone under favorable conditions to cause meningitis were often present in even the healthy pharynx. The instances of local bacterial action upon the nervous system were few, while, on the other hand, the nervous system was

especially prone to suffer from toxic agents in the blood. Several of them had a strong tendency to attack the vaso-motor system and by disturbing the circulation prevent that normal vascular dilatation so necessary for the protection of the body against the invasion of pathogenic organisms. In tetanus the irritability of the spinal cord was heightened, as in strychnine poisoning; in diphtheria, the cardiac centers were sometimes involved, though gross lesions might be absent; in influenza the tendency of the poison was toward the brain more than in the case of some of the analogous diseases.

In conclusion, the speaker said that in the future much would be gained by directing the line of research into classifying the special liability on the part of the nervous system to disease, independently of infectious processes, and to a refinement of our method of histological and bacteriological research.

The Relation of Infectious Processes to Mental Disease. -Dr. Charles K. Mills, of Philadelphia, in a paper on this subject, said that nearly a century ago Rush had declared that certain cases, such as gout, consumption, pregnancy, and fevers of all kinds, produced madness by acting on the brain in common with the whole body. Regis and Chevalier-Lavaure, in a report to the Congress of French Alienists, in 1893, had distinguished mental disorders (1) due to infectious diseases, (2) due to visceral disturbances, and (3) associated with diathetic maladies. While not denying the origin of mental manifestations and even special types of insanity from other causes—such as traumatism, anæmia, exhaustion, and emotional shock-the speaker said he believed they were sometimes due to the action of infectious and toxic agents, and probably to specific microorganisms, although the last could not be regarded as absolutely proved. He recalled one case, out of many others in his experience, in which there had been acute delirious mania, with hyperæsthesia, active contractions, and a petechial eruption. The symptoms had been highly suggestive of cerebro-spinal meningitis; but the autopsy had revealed nothing, and the case had apparently been one of toxemia associated with anemia. In considering the analogies with nervous affections, not psychoses, or insanities, which were supposed to be of microbic origin, it was only necessary to refer to such diseases as multiple neuritis, some forms of myelitis, and chorea. The teachings of the recent epidemic of influenza were important in this connec-

One of the most valuable contributions to the ætiology and pathogenesis had been furnished by Rasori, who had described in detail a case of acute delirium and given the results of the autopsy and of a careful bacteriological examination. The inoculations with the subdural fluid had led to the development of the same micro-organism, and a series of inoculation experiments on rabbits had demonstrated that this bacillus obtained from the subdural fluid had produced a toxic substance which destroyed the rabbits with symptoms of septicæmia in a short time. Tuke and Woodhead believed that a considerable proportion of cases of puerperal insanity were due to toxic influence without reference to childbirth, and in a series of two hundred cases of eclampsia Olshausen had observed eleven cases of psychoses following eclampsia. It had been alleged that the eclampsia bacillus was the sole cause of puerperal eclampsia, and that this organism was found in no other disease.

5t

(co

The following were the author's conclusions: 1. That specific infection must be included among the causes of the mental symptoms and disease which precede, accompany, or follow febrile and other infectious disorders. 2. That much negative evidence could be adduced in favor of acute delirium or acute mania being due to toxamia. 3. That analogies with nervous affections known or believed to be of microbic origin favored

the view that insanities with similar or related phenomena and lesions were also microbic in origin. 4. That the meager evidence that had been afforded by careful bacteriological investigation of cases of acute insanity had seemed to show that various micro-organisms might induce the same or similar types of mental disease. 5. That the mental disorders of pregnancy and the puerperal state were in a considerable proportion of cases probably toxemic, without reference primarily to childbirth; but it could not be regarded as proved that a bacillus of either celampsia or puerperal mania was the sole cause of these affections.

Dr. Francis S. Dercum, of Philadelphia, continued the discussion with some remarks on the therapeutics of the subject. He said that a consideration of the treatment of infectious nervous processes involved not only the treatment of the infection. but also its prevention. From much that we knew we had reason to believe that the occurrence of infection was markedly influenced by the nervous system. The ability to resist infection depended largely on the maintenance of nervous tone. We had also learned that the nerve cells underwent certain changes in the course of their functional activity, and these changes could only be interpreted as those of fatigue. The first problem was the prevention of undue waste of nervous substance from excessive fatigue. The necessity of a proper proportion of sleep and exercise and of suitable food was to be borne in mind as an important element in prophylaxis. There were some doubts about the efficiency of the preventive inoculations practiced by Pasteur, Behring, and others. In regard to treatment, the general indication was to arrest or limit the infectious process and to bring about elimination of the morbid product. To meet the first indication was not as yet possible, but the field of chemistry and of the biological laboratory might in the future yield great discoveries. With the possible exception of tuberculosis and lepra, the symptoms produced by infectious micro-organisms appeared to be due not so much to the germs as to the toxines. In the treatment of tuberculosis of the nervous system Koch's lymph had been shown to be not only useless but dangerous. The same remark applied with almost equal force to the treatment of leprosy. From a consideration of the literature of the subject the speaker was convinced that it was vain to deny the truth of Pasteur's experimental researches on animals, while the evidence regarding human beings in specific instances was strong and convincing. The speaker said that he had collected thirty-four cases of tetanus treated either with Pizzoni's powder or with serum. Of these, twenty cases had been successful, but in some of them other measures, such as amputation or early active treatment of the wound, had been employed. There was no contraindication to the employment of these antitoxines, as it seemed to be in no way injurious.

The other means at our disposal for combating the infectious nervous processes resolved themselves into general remedies, drugs, and surgical procedures. Cold had been applied with varying success. It was not improbable that baths of suitable temperature might prove of service in the treatment of infectious nervous diseases. Whether or not by this means the elimination of toxines would be favored was a matter that at present could only be conjectured. The results of the use of drugs in these diseases had so far been very discouraging. Surgical procedures enabled us occasionally to accomplish definite and brilliant results. This was especially true with regard to the evacuation of pus in positions formerly considered inaccessible, as in brain abscess.

In conclusion, the author offered a suggestion in regard to the treatment of tetanus which he thought might prove of value. It had been observed that the tetanus bacillus while growing in thymus infusion did not develop spores, and that animals subjected to such cultures were highly proof against the cultures grown in other media. If thymus juice possessed such remarkable properties, it should be tested with a view to its possible therapeutic effect. Its administration beneath the skin in a case of tetanus would certainly do no harm, and might do good, and it might also be administered by the mouth. If successful, it would prove far more valuable than the antitoxine, because it was so readily procured.

SOCIETY OF THE ALUMNI OF BELLEVUE HOSPITAL.

Meeting of April 4, 1894.

The President, Dr. FREDERICK HOLME WIGGIN, in the Chair.

(Concluded from page 633.)

An Osteosarcoma involving an Anterior Cranial Fossa, and an Epithelioma of the Larynx.—Dr. Charles Phelps read a paper with this title. (See page 775.)

Dr. J. W. S. Gouley said that he fully indorsed what the author had said on the subject of the early extirpation of tumors. He would refer to a case of villous tumor of the larynx which he had removed in 1867 from a child six years of age. It had been, of course, regarded as a benign tumor. The patient was still alive and in good health. Two other cases in later life had been operated upon by a surgical friend and had proved to be malignant, and the patients had died soon after. In the case of the child referred to, he believed that had the tumor been less slow in growth, so as not to have obstructed the breathing, it would in time have become malignant.

He had examined the tumor in Dr. Phelps's case with great care and interest. Certain transverse sections of the projections of the villi had shown a beautiful ingrowth of the epithelium; but in other transverse sections there had been fibrous tissue, and an absence of malignant transformation. In talking over the case with Dr. Dunham, he had found that they agreed in the opinion that the change had probably not begun until about four months before the operation. This had shown that if a tumor were appreciable to the eye and accessible to operation, the sooner it was removed the better.

Traumatic Aneurysm of the Dorsal Artery of the Right Foot,—Dr. J. W. S. Goulev read a paper with this title. (See page 777.)

Dr. J. A. WYETH said that the surgical treatment of aneurysm was a vast subject. With the additional light of modern surgery, particularly with the aid given us by catgut, a clean excision of an aneurysm of the arm, hand, or some parts of the shoulder and neck, was the ideal treatment. It seemed to him that in Dr. Gouley's case nothing else could have been done, for deligation and the formation of an organized clot would have for years prevented the patient from wearing an ordinary covering for the foot. It seemed also that if by the use of a tourniquet it had been possible to make a clean dissection of the aneurysmal tumor, this would have been better. He had never seen a case of aneurysm of the dorsal artery of the foot-in fact he did not remember to have seen an aneurysm of any of the arteries of the foot or ankle. Aneurysms of the popliteal space had been treated by excision. Recently his assistant, Dr. Van Arsdale, had excised such an aneurysm. The case had been sadly instructive, inasmuch as gangrene had supervened, and the patient had succumbed to the gangrene. This had taught him that if he had to operate upon an aneurysm in this space he would be very careful in determining whether he would treat it by deligation on the cardiac side, or by compression, or by position; he certainly would be careful about dissecting out an aneurysm in this place, for it was well known that there was very little collateral circulation to rely upon, and there were

several articular branches destroyed by such dissection. Simple deligation might cause the formation of a clot, and yet not completely interrupt the circulation through these articular arteries. In the case just referred to, he thought that gangrene had been due to a too wide dissection, thus interfering with these important vessels. In the thigh, he saw no necessity for complete extirpation of the aneurysmal sac unless the tumor was so large that it interfered with the function of the limb. In the upper extremity, he had seen aneurysm of the radial artery, and here, as he had said, the ideal treatment was excision. In the forearm, the arm, the shoulder, the axilla, and in aneurysms of the subclavian artery, this operation had been done. It was indicated in aneurysms of the subclavian and axillary arteries where there had been much organization of fibrin within the aneurysm, and where there was considerable pressure exerted on the axillary plexus or the brachial plexus. Recently Dr. Mc-Burney had performed an extensive dissection and removed such an aneurysm of the subclavian artery. Such extensive dissection could not always be done, and was not always necessary. He had once treated an aneurysm of the internal carotid artery which had extended from the entrance of this vessel into the petrous portion of the temporal bone down near to the common carotid artery. He had tied the common carotid and then the external carotid below the origin of the facial, leaving only the superior thyreoid, which he had deligated, thus completely cutting off the circulation through the internal carotid artery. This had been done some ten or twelve years ago, and on examining the case a few days ago, he had found that the tumor had entirely disappeared.

There were special aneurysms about the root of the neck and arch of the aorta in which this operation was contraindicated. These aneurysms were very formidable, and all sorts of devices had to be resorted to to secure proper coagulation. He had tied the subclavian and carotid arteries in several instances on the distal side of these aneurysms. There was no doubt but that the distal deligation after the method of Wardrop and Brasdor did have a solidifying effect on the aneurysmal tumor, but it did not follow in all cases. In a case occurring in his practice within the last two years, he had carried out the suggestion of Macewen, of Glasgow, with a very happy result. A young sailor with a specific history had come to him with a large aneurysm of the ascending arch of the aorta. It had appeared on percussion to be of the size of the two fists. It had pushed the clavicle upward, projecting two inches beyond the level of the chest, and had cut two or three ribs in two, so that the sac had appeared to be about a quarter of an inch below the skin. The man had been almost moribund when seen. He had been given large doses of iodide of potassium, but his condition had been so grave that this treatment had been too slow. A number of harelip pins three or four inches in length had been boiled, and then the sac had been filled with these pins just as if it had been a pincushion. A still longer needle had been boiled in the same way, and had been thrust into the sac, and had been used to tease the coagulum within the sac by scratching the walls of the aneurysm. The other pins had been left in for eighteen hours. Within forty-eight hours the tumor had been found to be decidedly less elastic. A week later this procedure had been repeated. The man had eventually recovered, and had been up to two months ago engaged at his old occupation of a carriage painter.

The speaker said he had never treated any aneurysms by incision into the sac, but he would always be afraid of suppuration in these conditions.

Dr. Phelps said that if he had understood the author and the last speaker correctly, he thought they were speaking of different subjects—the reader of the paper on traumatic aneurysm and the last speaker on idiopathic aneurysm. In traumatic aneurysms he would say that it seemed to him that the artery should be tied above and below the aneurysm, and as closely as possible to it, and he knew of no way of getting closer to it than to go into it; having done this, he saw no objection to removing it. This remark, of course, did not apply to idiopathic aneurysms.

Dr. PARKER SYMS said that he, too, thought we should make a careful distinction between traumatic, idiopathic, and diffuse aneurysms, and also as to their situation. In traumatic and diffuse aneurysms the treatment by incision and dissection of the sac as far as possible was the best. He had treated three cases of diffuse aneurysm in this way-two of the femoral artery and one of the lower portion of the popliteal artery. One of the femoral aneurysms had been directly due to a fall: the other had been apparently an idiopathic aneurysm superinduced by resting heavy weights upon the upper part of the thigh. In these aneurysms the pulsation had ceased and the aneurysm had rapidly increased in size. In one case the clot after removal had weighed three pounds. He thought that his cases demonstrated that it was not necessary to tie the distal end of the artery. Owing to the fact already stated that in the popliteal space the collateral circulation was poor, he had probably made a mistake in his third case in ligating the artery near the site of the aneurysmal tumor. This patient had died of sloughing into the popliteal space and secondary hæmorrhage. Certainly where an aneurysm was in such a position that it could be readily dissected out, it should be so treated even if it were an idiopathic aneurysm. Deligation only resulted in the formation of a hæmatoma, which often subsequently caused a good deal of trouble. Treatment by compression did not seem to him to be any safer or better than the other methods. The speaker recalled a case of popliteal aneurysm seen in Bellevue Hospital in 1879 which had been treated by compression. The patient had died of gangrene after consolidation had taken place.

Dr. Lucius W. Hotchkiss said that he had presented to the society two or three years previously a traumatic aneurysm of the palmar arch which he had removed complete. This seemed to him the ideal method in the treatment of small aneurysms of the extremities.

With reference to the rarity of idiopathic aneurysms of the dorsalis pedis artery, he said that Dr. Gouley would probably be interested to know that he had last winter in the Colored Hospital seen one such case of idiopathic aneurysm.

Dr. Goulky said that he had made the statement in his paper that diffuse aneurysms demanded incision at least, because a diffuse aneurysm, according to the experience of many observers, was bound to become a huge abscess. It should be laid open and cleansed just like an abscess. If possible, it should also be excised. John Bell had been really the first to formulate this statement. It should be incised not because it was an aneurysm, but because it was a dead aneurysm, and it should be dealt with as if it were a foreign body. He would not be willing to advise excision of a diffuse popliteal aneurysm, but he would certainly incise it. The chances were that the distal end in this case would be plugged. The proximal end should be tied, and there was little chance of bleeding from the branches given off by the artery where it had become dilated; in fact, the earlier surgeons who treated traumatic aneurysms by incision did not tie the vessel; they plugged the end of the vessel with paper pulp rendered aseptic with alcohol or other substances. Mr. Syme had not cut into that huge axillary aneurysm as a primary object; he had only made an opening sufficiently large to enable him to introduce and plug the subclavian artery with his finger. A ligature had been then applied, and the aneurysm had been laid freely open. It had been as bold a procedure as it had been a brilliant success.

The speaker said that he did not think it was necessary or expedient to lay open every idiopathic aneurysm; where there was much disease of the artery he would prefer to treat it by compression, or else by a very distant ligature.

His object in the paper had been to call attention to the great importance of freely laying open diffuse, dead aneurysms.

# Reports on the Progress of Medicine.

#### OTOLOGY.

BY CHARLES STEDMAN BULL, M. D.

Osteoma of the Mastoid,—Green (Arch. of Otol., xxii, 3) reports two cases of this rare anomaly. They both presented appearances entirely different from the ordinary exostoses and hyperostoses. The tumors lay just within the orifice of the meatus and evidently arose from its posterior wall. On superficial examination they appeared firmly attached, but by careful pressure a very slight movement was perceptible. Both proved to be growth of true bone, oblong and covered throughout, except at two minute spots, with tissue-one with cartilage and the other with fibrous tissue. Both were situated in the anterior and outer part of the mastoid, but not attached to that bone, and both were lying in carious cavities. There was no history of earache or otorrhea for months or years before, but merely the history of deafness of several years' duration, coming on without any symptoms; then for a few weeks gradually increasing pain, discharge, and swelling about the ear. In neither case was the drum membrane perforated, although it was enormously swollen. No sign of any adhesions of the tumors to the bone could be made out.

A Contribution to the Anthropology of the Ear in Criminals. - Daac (Arch. of Otol., xxii, 4) has drawn the following conclusions from his investigations: 1. The length, breadth, and base of the ear increase with age. As the length increases more than the breadth, the physiological index becomes smaller. 2. The three distances from Darwin's tubercle to the base line decrease in age. This decrease must be due to the fact that in age the ear projects farther from the head than in youth, or that the helix margin shrinks with age. 3. Up to the thirtieth or fortieth year the length of the ear decreases as compared with the height of the individual; in other words, the individual grows relatively faster than the ear. From thirty or forty on the ear grows, while the individual becomes smaller. 4. The results are in perfect accord with the measurement of the ears of normal individuals. The size and form of the auricular cartilage vary in the same individual with age. The projection of the ear from the head increases with age. The auricular cartilage of Norwegian criminals seems to be smaller that that of normal Germans, and the ear is smallest in Lappish criminals. There is no type of auricular cartilage which may be considered the "criminal ear."

Contribution to the Microscopic Anatomy of the Human Nasal Cavities, particularly of the Olfactory Mucous Membrane.—Suchannek (Arch. of Olol., xxii, 4) recognizes in the human olfactory nucous membrane, in addition to the supporting fibers, typical olfactory and basal cells. 1. Genuine leucocytes, ninepin-shaped and oval, with hyaline contents. 2. Cells which resemble leucocytes, but which prove to be cellular elements with a pedicle. 3. Transition cells from the pigmented "bell cells," having a small amount of pigmentation and hya-

loid contents. He has never seen this form except in cases of diabetes mellitus, and he leaves it an open question whether they are normal or pathological. 4. Distinctly pigmented, round, long, or transversely oval cells, the longitudinal axis being generally parallel to the longitudinal axis of the rest of the epithelial cells. He calls these migratory cells.

An Unusual Case of Bilateral Fracture of the Temporal Bone.—Vulpius (Arch. of Otol., xxii, 4) reports a case of unusual interest in a man who fell a distance of twelve feet, striking on his head. On recovering consciousness, he noticed bleeding from his nose and mouth. For about three weeks he could not walk, and suffered from severe headaches and dizziness. His right eye was closed by a swelling, and there was a wound at the back of the right auricle. There was complete facial paralysis of the right side. There was a loss of taste at the anterior part of the right side of the tongue, which suggested that the fracture of the temporal bone on the right side had probably passed between the origin of the large petrosal nerve and the branching off of the chorda tympani. There was no evidence of any bleeding having taken place from the ear on the mainly affected right side, while on the left there was a blood clot and local marks of ear bleeding, even after some weeks had elapsed.

A Case of Removal of the Stapes.—Bezold (Arch. of Otol., xxii, 4) reports the case of a woman, aged forty-eight years, who had suffered from deafness for a year with constant tinnitus. In both ears there was a perforation of the drum membrane with purulent discharge. The operation for removal of the right stapes was done under cocaine, and at the moment of removal the patient sank on the other side and became pale, but retained consciousness. Excessive giddiness lasted three days. She then complained of tinnitus. The ear remained dry. The result of the operation for the first few days was absolute deafness. After three weeks some hearing returned, but remained always much less than before the operation.

Removal of the Stapes.-Blake (Arch. of Otol., xxii, 4) holds that the operation of removing the stapes does not answer the purpose which might be hoped from it in cases of chronic non-suppurative disease of the middle ear. For this class of cases he advises an exploratory tympanotomy with local anæsthesia only, as preliminary to an operation having in view any form of interference with the middle ear. The exploratory tympanotomy affords an opportunity for a better determination of the condition of the middle ear in a chronic non-suppurative disease than can be determined in any other way. In the great majority of cases of stapes fixation, consequent on chronic nonsuppurative disease of the middle ear, the operation was ineffectual so far as the removal of the stapes was concerned, the fixation being such as to result in fracture of the crura instead of the removal of the ossicle entire. In all cases of nonsuppurative disease in which the stapes was extracted entire, the hearing was definitely improved in one ear only. The operation of stapedectomy does not afford a promising outlook for this class of cases. In suppurative diseases of the middle ear we have to deal with a different pathological condition; and while the extraction of the stapes has undoubtedly effected a considerable degree of improvement in some of the suppurative cases, it does not follow that equally satisfactory results could not have been obtained by the minor operations effecting a mobilization of the stapes or of the ossicular chain as a whole.

A New, very Efficacious Remedy for Local Infectious Pyogenic Processes in the Ear.—Cozzolino (Ann. des mal. de Voreille et du larynx, November, 1893) recommends the employment of microcidine in suppurative processes in the ear. It is composed of  $\beta$  naphthol and caustic soda, and is inodorous, cheap, and convenient. It appears as an ashy-colored powder,

soluble in water in the proportion of one to three and in alcohol, but insoluble in chloroform. By its physical, chemical, and physiological properties and by its alkaline reaction, microcidine neutralizes the irritating products of acid decomposition. Its antiseptic properties rank it next to corrosive sublimate. By its application, suppurative discharges are healed in three or four days, even when the drug is used in strengths of three or four per cent. It does not irritate the tissues.

A Point in the Physiology of the Stapes.—Gellé (Ann. des mal, de l'oreille et du larynx, December, 1893) calls attention to the following point: The stapes moves toward the labyrinth whenever the drum membrane is pushed inward, and this movement has been studied and measured. Slight, rapid pressure made upon the drum membrane by means of a pear-shaped air bag fitted to the sound ear modifies immediately and profoundly the sensation of a tuning fork vibrating on the skull; and each push or pressure soon causes a weakening of the sound, which regains its intensity when the pressure ceases. A series of movements or pressures imprinted upon the conducting apparatus and transmitted from the drum membrane to the base of the stapes are therefore the cause of a temporary diminution in the sonorousness of the sound. Here we have a delicate function of protection, and the instrument which gathers the sound possesses the power of weakening the intensity to a certain extent. At the threshold of the labyrinth, that portion of the sound-conducting apparatus diminishes its intensity. Some pathological conditions cause permanent immobility of the base of the stapes, and the principal sign of this immobility is the impossibility of modifying the sensation of the tuning fork in vibration at the apex by centripetal pressure. The so-called "dampers" of the ear are many, and the central nervous system contributes as much to them as does the peripheral apparatus for the reception and transmission of the waves of sound. The two organs operate together for the purpose of protection.

New Method of Treatment of Absess of the External Auditory Canal by Intubation.—Courtade (Ann. des mal. de Voreille et du larynx, December, 1893) defines the term "intubation" as used here as the introduction of a rubber tube into the canal, to serve both as a drain and as a permanent dilator. He uses it in the treatment of abscess of the external auditory canal, and in membranous obstruction of the canal. After the tube has remained in the canal for several days and sufficient dilatation has been produced, the tube may be removed and the canal tamponed with iodoform gauze. This maintains the canal in an aseptic condition and each time the gauze is removed the canal can be irrigated with a solution of camphorated salo.

The Bony Prominence of the Auriculo-facial Region of the Ear. - Gellé (Ann. des mal. de l'oreille et du larynx, January, 1894) draws the following conclusions from his observations: 1. The tympanic cavity and the mastoid cells are separated incompletely above, totally below for the lower two thirds, by a compact, bony lamella, which forms the posterior wall both of the external auditory canal and of the drum. Both these cavities may be filled simultaneously, but they can be emptied independently of each other. 2. Considering the pathogenetic importance of this bony partition, the name "bony prominence of the facial" aptly characterizes it. 3. The Falloppian canal traverses this prominence from above downward and from within outward, and is divided into three portions: an intratympanic portion, a tympanic portion, and a mastoid or extratympanic portion. 4. The point of intersection of the canal with the posterior border of the tympanic ring corresponds to the main horizontal diameter of the drumhead. At this level the facial is situated at two to three millimetres from the surface of the auditory canal. 5. In its extratympanic course the

Falloppian canal runs along the posterior wall of the auditory canal, from two to four millimetres from its surface. 6. The thickness of the osseous lamella which forms the posterior walls of the canal and drum is very unequal. 7. A section perpendicular to the temporal surface of the skull, on a level with the auditory canal and toward the posterior border of the tympanic ring, cuts the Falloppian canal and posterior wall of the drum and opens the mastoid hiatus between the antrum posteriorly and the attic anteriorly. 8. By opening the bottom of the auditory canal through the supero-posterior wall three millimetres behind this proposed line of section, we reach the mastoid antrum without touching the facial. 9. By opening the canal in front of this proposed line of section, at four or five millimetres above the tympanic ring, we come down upon the wall of the cell of the ossicles and open the attic. 10. The margin of the mastoid antrum is six to eight millimetres behind this line, and on the other side is the lateral sinus. 11. The opening of the antrum must be made through the mastoid, if it is to be of any service. 12. The opening of the attic is facilitated by the guidance of this proposed line of section, and in front of it the superior wall should be removed for a distance of five millimetres from the tympanic ring. 13. The presence of this bony partition wall, incomplete above, aids in the formation of a close pathological connection between the drum, the mastoid cells, and the antrum, while it aids largely in separating them from each other, when it comes to a question of local treatment by irrigation, drainage, and disinfecting applications. The canal drains especially the tympanic cavity. The obstacle is this bony facial prominence, which can not be avoided in its tympanic portion. Hence the necessity of creating a special artificial channel by which to drain and treat the cavities behind it. Hence the retention of pus, caries, osseous fistulæ, sequestra from this projection, and lasting otorrhea, with its complications of grave facial paralysis and trifacial neuralgia. 14. Facial paralysis may complicate suppuration of the mastoid without apparent bony lesion either in the canal or posterior wall of the tympanic cavity. 15. The facial is involved in the various lesions of the bony protuberance. 16. Facial paralysis may be observed in otorrhea accompanying the osseous lesions of the bottom of the canal. Fistulæ of the posterior wall of the canal are frequent, as well as polypi in the fistulous tracts, and the removal of the latter may be followed by facial paralysis. 17. The presence of the facial nerve in this region paralyzes the efforts of the surgeon; but the gravity of the lesions and their complications may often make it necessary to sacrifice the nerve. 18. When sequestra are present, it is better to wait till they are freely movable before attempting their removal. 19. In the operation of curetting the various fungous and osseous surfaces, it is well to touch very lightly on the bony prominence, because of the danger of wounding the facial. 20. In injuries of the skull, the result of falls, with hæmorrhage from the ear and facial paralysis, the lesion may be limited to a crushing of the canal of Falloppius, with compression of the nerve by hæmorrhage, the hearing returning when the canal is reopened, and the paralysis disappearing after the absorption of the blood.

Furunculosis of the External Auditory Canal.—Barret (Ann. of Ophth. and Otol., July, 1893) thinks that the local abstraction of blood by means of one or two leeches applied to the tragus may be of service, though rarely necessary. A brisk purge will effect sufficient depletion, and should be one of the first steps in the treatment. Dry heat, in the form of hot flannels, a hot salt bag, or a hop pillow, applied to the ear, is the best way to relieve pain. The surface of the swelling should be covered with an ointment made of extract of arnica and belladonna, each twenty grains, to the ounce of lanolin.

pledget of cotton is then inserted into the canal as tightly as it can be borne and left there as long as possible. This must be repeated each day until the furuncle has disappeared. Sometimes a ten-per-cent solution of menthol introduced on cotton pledgets will soon relieve the pain, and new furuncles do not appear. The menthol is considered to arrest the development of the Staphylococcus pyogenes aureus and the Streptococcus pyogenes.

The Treatment of Chronic Suppuration in the Middle Ear by Removal of Carious Ossicles, Necrosed Bone, and other Obstructions in the Tympanum,-Würdemann (Ann. of Ophth, and Otol., January, 1893) considers that the treatment of chronic suppuration in the middle ear should be on the same lines that govern our procedures for suppuration in other parts of the body. We should endeavor to remove the cause and obtain free drainage. The removal of the carious ossicles, necrosed bone, and other obstructions to free drainage in the attic of the tympanum is very easily done through the canal. Polypi and granulations should be removed wherever found. The operation done through the canal gives seventy per cent. of radical cures, fully half of the remainder being cured by subsequent treatment, and the rest being greatly benefited by the better drainage. This operation has the advantage of destroying but little of the healthy tissues, and in fully fifty per cent. of the cases the hearing is improved; whereas, after the mastoid operation there are but few cases in which the hearing is improved, and many are made worse.

Removal of the Ossicles, -Sheppard (Ann. of Ophth. and Otol., October, 1893) draws the following conclusions from his own observations and the experience of others: 1. Cocaine can be used with advantage as the anæsthetic in a considerable proportion both of suppurative and catarrhal cases. 2. Removal of the malleus alone is not, as a rule, sufficient in either class of cases. 3. Removal of the malleus and incus will cure a arge majority of the suppurative cases, and improves hearing n about half the cases. 4. Removal even of all three ossicles will sometimes fail to cure middle-ear suppuration. 5. Removal of the stapes entire gives better results than when the foot-plate is left in place, although a moderate proportion of the latter class show very good results. 6. Reactive inflammation seems as likely to occur in cases of partial excision of the membrana tympani as in total excision with removal of all the ossicles. 7. Unpleasant symptoms, such as severe and prolonged dizziness, vomiting, facial paralysis, and meningeal irritation, occur in about a fourth of the cases. 8. In a majority of cases the tinnitus has remained unchanged.

The Treatment of Tinnitus in Aural Sclerosis. - Seiss (Ann. of Ophth. and Otol., January, 1894) has found oil injections and the direct application of the vapor of menthol to the tubal lining especially useful in tinnitus of catarrhal origin. The oil best suited for the purpose is pure fluid albolene, to which may be added camphor or menthol in the strength of half a grain to two grains per ounce. A full-sized Eustachian catheter, a one-drachm syringe fitting the former on the ground-joint principle, and an ordinary catheter inflation bag adapted to the same, are the instruments required. The catheter is introduced in the ordinary way and firmly fixed in the Eustachian orifice; the syringe is then filled with oil slightly warmed, fitted to the catheter, and its contents forced into the tube; the syringe is then promptly withdrawn and air inflated through the catheter to gently force the oil farther up the tube. The action of the remedy seems to depend on the well-known vascular sedative effect of the medicament used, as well as upon the general mechanical and lubricating action of the oil. Menthol vaporization has been used by the writer with excellent results in stopping tinnitus and other aural symptoms dependent on tubal congestion and inflammation, and he prefers the Dench vapor generator. The bottle is half filled with fresh menthol crystals, the catheter is then passed and fixed in the Eustachian tube, the cone tip adjusted, and the bulb compressed, when the vapor passes through the catheter into the tube and is at once perceived by the patient. To produce a direct effect on the vascular supply of the tympanum, the author has obtained the best results by freezing the mastoid region over the branches of the posterior auricular and stylo-mastoid arteries. For this purpose he uses the tubes of ethyl chloride, which opened and held horizontally, a very fine jet of fluid at once issues from its tip, which is to be directed on the mastoid region until the skin is frozen white over the whole area.

For the operative relief of tinnitus the author employs mobilization of the ossicles, the principle of the Siegle masseur being supplemented by mechanical force, and the ossicles liberated to a greater or less extent. This method has the advantage of perfect safety, comparative painlessness, and can be performed several times upon the same car without injury. It rarely fails to relieve subjective noises for at least as long a time as the most radical excisions.

On Systematic Procedure in Operations for the Reliet of Intracranial Disease Secondary to Ear Suppuration.—Pritchard (Arch. of Otol., xxiii, 1 and 2) lays down the following rules for operating in these cases: 1. First thoroughly open the antrum and explore the mastoid cells. 2. Failing to find sufficient evidence to account for the whole of the symptoms, the wound in the skull should be enlarged backward so as to expose the middle and posterior fossæ above and below the lateral, which should be explored by means of a hypodermic syringe. At the same time subdural abscesses may be carefully looked for. 3. If a clot is found in the sinus, the internal jugular vein should now be tied and the sinus opened and thoroughly cleared of its contents. 4. If there is any suspicion of cerebral or cerebellar abscess, exploratory punctures may be made above and below the sinus, and the pus, if found, evacuated.

Exploration of the mastoid cells and opening the antrum is a matter of prime importance, for if neglected the surgeon is apt to leave untouched the very origin of all the mischief, and if this does not prove fatal to the immediate success of the case, there is always the danger of subsequent infection. In enlarging the wound in the skull Pritchard uses the chisel, mallet, and Hoffman's gouge forceps. If the trephine is employed care should be taken that the trephine opening should be made continuous with the antral opening, so that the intermediate point should not be missed. In this step of the operation the lateral sinus is to be exposed with the dura mater immediately above and below it, and thus access is gained to both the middle and posterior fossæ of the skull. Careful search should be made for collections of pus between the dura mater and the bone, and it any extensive extradural abscess be found the cranial opening must be enlarged. In the event of a thrombus being found in the sinus the point of ligation of the internal jugular vein should be well below any clot that may be felt in the vein itself, and it may be advisable to dissect out a length of the vein. The sinus should be freely opened and the contents thoroughly removed by means of the syringe and sharp spoon, free bleeding from the upper end of the sinus being encouraged.

Purulent Otitis Media leading to Caries of the Temporal Bone; Epimeningeal Abscess and Death, while the Mastoid remained Intact.—Reuling (Arch. of Otol., xxiii, 1 and 2) reports a case of this sort in a man, aged fifty-seven. At the autopsy marked hyperamia of the whole right side of the brain was found, and, on lifting the right temporal lobe, about two tablespoonfuls of bloody pus were found in the fossa temporalis and along the pyramidal bone. The inner wall

of the squamous bone was perforated by many small fissures, which broke down easily and left an irregular, rough-edged hole of six lines long and five lines broad, communicating through the thickness of the squamous bone with an opening of about the same dimensions, and situated directly over the upper wall of the external auditory canal. There was also a pus cavity extending almost an inch horizontally between the diploë of the squamous bone toward the mastoid process, ending blindly without entering the cells. Along the upper ridge of the pyramidal bone was extensive caries. The brain on the right side was very soft and brittle, and the lateral sinus was filled with about twice the usual quantity of serum. There was no abscess in the brain substance and no distinctly formed thrombosis of the sinus.

A Case of Ankylosis of the Stapes and a Case of Nerve Deafness, with Manometric Examinations and Autopsies.— Bezold (Arch. of Otol., xxiii, 1 and 2) compares the clinical histories of these two cases as follows: The first showed the three cardinal symptoms of a marked defect in the motility of the conducting apparatus-viz., negative Rinné, prolonged bone conduction for low tones, and a large defect at the lower end of the scale for air conduction. The second case was functionally the opposite of the first. Only a small portion in the middle register was preserved for air conduction; bone conduction was completely wanting and Rinné in the other ear was positive. The fixation in the conducting apparatus in the first case was due to a bony ankylosis of the foot-plate of the stapes, affecting a considerable portion of the annular ligament. The nerve deafness in the second case was found to be due to atrophy found in the first and second turns of the cochlea. Both cases illustrate the necessity of examining the ear with the continuous tone series and also of comparing the air and bone conduction.

A Case of Primary Tuberculosis of the Mastoid Process. -Knapp (Arch. of Otol., xxiii, 1 and 2) reports a case of this kind in a child, aged five, of scrofulous habit. The child had several large ulcers in various parts of the body, two being in the vicinity of the eyelids. The right mastoid and supra-auricular portions of the temporal bone were swollen, ulcerated, granulating, and discharging fætid pus. Both auricles, external auditory canals, tympanic membranes, and middle ears were perfectly normal, and the hearing in both ears was unimpaired. Knapp removed extensive pieces of necrosed bone from both orbits, including a portion of the left zygoma. He then made a curved incision one centimetre behind the insertion of the right auricle, four centimetres long, down to the bone, from the zygomatic ridge of the squamous bone through the linea temporalis as far as the tip of the mastoid. The bone was carious and several fistulæ led to the interior. The whole outer table of the mastoid was chiseled away. Its interior and the adjacent part of the squamous bone were a mass of decaying bony tissue, which was broke down and carefully removed with a sharp spoon. All the wounds were washed out with a solution of mercuric bichloride (1 to 5,000) and tamponed with subblimate gauze, and were syringed and dressed daily and healed in a few months.

The Percussion of the Mastoid Process, with the Report of a Recent Case of Diabetic Caries of the Mastoid.—
Koerner and von Wild (Arch. of Otol., xxiii, 1 and 2) have concluded from certain investigations that the air contained in the mastoid has no effect on the resonance. The percussion sound depends much more on the resonance of the healthy or diseased bone substance itself. They use a small metal hammer for percussion, which must always be comparative. The striking surface is eight millimetres broad and slightly convex. The handle is sixteen centimetres long and is made of a thin, tapering piece of whalebone. With this hammer, by moderately

forcible, even painful percussion over normal bone covered by thin skin, a loud, clear, osseous tone can be obtained. A place is to be chosen on the mastoid: 1. Below the linea temporalis, as this line denotes approximately the upper border of the mastoid. 2. Above the insertion of the tendon of the sterno-cleidomastoid muscle, because this thickens the covering over the bone. 3. Behind the border of the auricle. 4. In front of the insertion of the hair. Comparative percussion, of course, allows of a conclusion as to the condition of the bone only when the soft parts are unaltered. A one-sided perforation or accumulation of pus within the tympanum has no effect on the percussion note.

In experimenting on the cadaver the skull must be sawed through symmetrically and higher up than usual. A hole is then bored through the dura and tegmen mastoidei, and from this hole other holes are bored out in different directions, thus opening up many cavities. These cavities are then injected with melted paraffin under strong pressure. After the solidification of the injected mass, percussion shows no difference from that which existed before the boring of the holes. It is evident from these experiments that a filling of the air spaces in the mastoid does not affect the resonance, and that, on the contrary, a hollowing out of the bone diminishes the resonance. The authors conclude as follows: By means of Lücke's bone percussion it is possible to recognize a central osteitis of the mastoid at a time when the disease betrays itself by no externally perceptible sign. It is the disease of the bone itself and not the obliteration of its air spaces that alters the resonance.

# Miscellany.

The Medical Corps of the Marine-Hospital Service.—In an address recently presented by Surgeon-General Walter Wyman before the Committee on Inter-State and Foreign Commerce of the House of Representatives, on the matter of a bill to establish a bureau of public health in the Department of the Interior, we find the following interesting account of his corps:

"The medical corps of the Marine-Hospital Service, as will be seen by the small blue book before you, consists of a supervising surgeon-general, sixteen surgeons, twenty-six passed assistant surgeons, nineteen assistant surgeons, and ninetythree acting assistant surgeons, making a total of one hundred and fifty-four. The regular corps, that is to say, all of the above excepting the acting assistant surgeons, are appointed by the President after thorough physical and professional examination. The acting assistant surgeons are appointed by the Secretary of the Treasury, on recommendation of the Supervising Surgeon-General, who satisfies himself as to the professional qualifications of the officer. The employment of acting assistant surgeons in times of emergency for temporary service, and the discontinuance of their services when the emergency is over, furnishes an excellent method of increasing or contracting the medical corps as occasion requires.

"The acting assistant surgeons are men who have been long in the service and are trained in Government routine. When newly appointed in emergency they are usually assigned to a marine bospital under the observation of the commanding officer and one of the older assistants, detailed to meet the emergency.

"I have heard that intimations have been made concerning the youth and inexperience of the members of the regular corps, the absurdity of which is shown by a table which I have caused to be prepared giving the age and date of graduation of Service relies upon the Marine-Hospital Service for the physical examination of its officers and men and their professional treatment when sick or disabled. The Life-Saving caused to be prepared giving the age and date of graduation of

every officer of the service. From this table it will be seen that the average age of the sixteen surgeons is fifty years, the average age of the twenty-six passed assistant surgeons is thirtyfive years, and of the nineteen assistant surgeons, twenty-nine years."

[The medical colleges represented are then enumerated, and the account continues as follows:]

"It will thus be seen that the members of this corps are fairly representative of the medical profession of the country. Many of them, in spite of the fact that they are subject to change of station every four years or oftener, have held and are now holding professorships in the medical colleges of the cities in which they are stationed.

"Concerning the new admissions to the corps, the law requires that they shall be appointed to the grade of assistant surgeon only, and provision is made for subsequent promotion. The examination is held once or twice a year, as occasion requires, and the applicant must pass a very severe test, making an average of eighty per cent. on all branches. The successful candidates are relatively few. For example, this month, out of twenty-nine who appeared for examination, only four made the required grade. These new appointees represent the very best men among the newer graduates of the colleges; but very rarely do they come direct from the medical college, most of them having had hospital or private practice before seeking admission to the corps. Out of the total sixty-one medical officers, fifty-three had hospital practice before entering the service, seven were engaged in private practice, and only two had neither private practice nor hospital practice.

"There are nineteen hospitals owned and operated by the service, and ninety-five additional relief stations, where at contract hospitals seamen\_are admitted and treated by acting assistant surgeons.

"The officers of the medical corps, just mentioned, are stationed in every important port on the coast, lakes, and rivers and, being trained in the execution of Government business, become valuable agents for the immediate execution of any sanitary measures which may be imposed upon them by telegraph or otherwise from the bureau. It is always possible for the Marine-Hospital Service, in any part of the country, on the shortest notice, to have qualified agents at a place of danger. There is scarcely an officer of the regular corps who has not had actual quarantine experience, and the corps numbers among its members men whose names have become national by reason of their effective service in various epidemics. The corps embraces a number of skilled bacteriologists, also men who have had large practical experience in the treatment of yellow fever and other contagious diseases, men thoroughly acquainted with all the military duties connected with sanitary cordons, detention camps, and with the methods of train and vessel inspections, scientific disinfection, etc. The effectiveness of this corps is the result of special care exercised to secure within it men who, by natural inclination and special education, are fitted for sanitary work, and is also the result of long and active experience.

"The Marine-Hospital Service dates as far back as 1798. It was reorganized and put upon its present basis in 1871. Though established for the purpose of caring for sick and disabled seamen of the merchant marine of the United States, there have been from time to time other responsibilities imposed upon, if, growing out of the necessities of other branches of the Government with which it is intimately and necessarily associated. For example, the Revenue-Marine Service, a branch of the Treasury Department, relies upon the Marine-Hospital Service for the physical examination of its officers and men and their professional treatment when sick or disabled. The Life-Saving Service relies upon the Marine-Hospital Service for the physical

examination of the keepers and surfmen. Hundreds of rejections of physically unsound men seeking to become surfmen have been made by the officers of the Marine-Hospital Service. The Steamboat-Inspection Service, a most important branch of the Treasury, relies upon the medical officers of the Marine-Hospital Service for a determination as to the ability of the pilots to distinguish signal lights, and large numbers of applicants for pilots' license are annually rejected by the officers of this service on account of color blindness. The Immigration Bureau relies by law upon the Marine-Hospital Service for the medical inspection of immigrants.

"Naturally, too, by reason of the intimate association of the Marine-Hospital Service, through its sailors, with shipping and commerce, the National Government has imposed upon this service the execution of the national quarantine laws, to which reference has already been made. I will only add here that, so far as national quarantine is concerned, the service, by tradition and constant activity, save for a period of four years, is the natural executor of the same. National quarantine received its first executive impulse through the first surgeon-general of the Marine-Hospital Service, Dr. John M. Woodworth, in 1878. Both prior and subsequent to this last date the bureau has controlled, wholly or in part, epidemics of yellow fever and of small-pox; notably yellow fever in 1873, 1876, 1877, 1878, 1882, 1887, 1888, and 1893, the Brunswick epidemic, when it was confined within the cordon on lines established by the service.

"It also took charge of railroad quarantine against smallpox in Canada, in 1885, and at Harris Neck, Ga., in 1891, it stamped out the disease.

"It had complete control of the quarantine measures against yellow fever in Texas in 1882, and in Florida in 1888.

"The Marine-Hospital Service has under its immediate control ten national quarantine stations, equipped with modern appliances for disinfection of vessels, hospitals for the care of the sick, and barracks, where required, for the detention of suspected immigrants.\* These stations are so far remote from populous centers as to be seldom visited, but their completeness and the scientific care exercised in isolation of the sick, the surveillance of those suspected and held under observation, the cleansing and disinfection of vessels, has excited the surprise and commendation of the few members of Congress who have visited one or more of said stations. There is a fleet of thirteen vessels connected with these stations, three of them being old vessels turned over from the navy for the purpose of receiving and housing people in quarantine.

"Now, referring to the work done by the Marine-Hospital Service for other branches of the Government—namely,the Revenue Marine, the Life-Saving Service, Steamboat-Inspection Service, and Immigration Service—a return service on the part of these branches of the Government adds to the strength and ability of the Marine-Hospital Service for quarantine work. For example, the Revenue-Cutter Service, under the same secretary as is the Marine-Hospital Service, may be called upon at any time, and frequently is, to assist in quarantine measures through the medium of their fleet of vessels. During the past summer revenue cutters have patrolled the Southern coast in aid of the quarantine cordon around Brunswick. They have carried medical officers and supplies to the Sea Islands, off the coast of South Carolina, in the sanitary work demanded of the Marine-Hospital Service by reason of the great storm. They have furnished

vessels for the Marine-Hospital Service repeatedly in New York Harbor, and in fact practically form a fleet subject to demand for service at any time in the aid of quarantine. During the past summer, when it was feared that the immigrant detention camps at Camp Low and at Delaware Breakwater, both under the control of the Marine-Hospital Service, might of necessity be occupied by immigrants held under observation, an arrangement was made with the Revenue-Marine Service for the immediate detail of their enlisted and armed men from the several cutters, to form the necessary guards around these camps, the places of the enlisted men to be supplied by new enlistments on the vessels.

"The Steamboat-Inspection Service, in return for the examination of pilots, furnishes experts to examine the hulls, boilers, and machinery of the vessels which belong to the Marine-Hospital Service.

"The Life-Saving Service, on request of the Supervising Surgeon General of the Marine-Hospital Service, is required by its superintendent to watch carefully for all dunnage and other stuff that might float ashore from infected vessels, thrown overboard before said vessels reach port; to gather up with rakes such material and burn it.

"The presence of medical officers at the immigrant reception stations at the several ports enables the bureau to keep fully informed with regard to immigrants and their baggage, which constitute so large a proportion of the danger in the matter of epidemic importation.

"The operations of the Marine-Hospital Service, independent of quarantine, during the fiscal year ended June 30, 1893, may be summarized as follows: Total number of sailors treated in the hospitals and dispensaries, 53,317; of which number 14,-857 were treated in hospital, the remainder being office or dispensary patients. There were 1,353 pilots examined for color blindness, of which 48 were rejected. One thousand and ninety-five surfmen and keepers of the Life-Saving Service were examined, of which number 41 were rejected for physical causes. Two hundred and seventy-nine seamen of the Revenue Marine were examined before shipment as to their physical fitness, and 22 were rejected.

"With regard to funds, the quarantine service is maintained by a yearly appropriation for the ordinary maintenance of the ten national quarantine stations. In addition to this there is what is known as the 'Epidemic Fund,' which is placed at the disposal of the President, to be used under his direction in any manner he sees fit, to prevent the introduction and spread of epidemic diseases. It is from this fund that the expenses of the foreign quarantine and extraordinary precautionary measures in this country have been paid.

"The Marine-Hospital establishment, independent of quarantine, is maintained by a continuing fund derived from the tax on foreign tonnage."

Formic Aldehyde as a Rapid Hardening Reagent for Animal Tissues.—In the British Medical Journal for May 26th W. McAdam Eccles, M. B., B. S., F. R. C. S., assistant surgeon to the West London Hospital, says:

"In the busy life of the present day the saving of time in all parts of medical work is of the utmost importance, and this is especially so in regard to microscopic pathology. Too often a portion of tissue, removed either for diagnosis or in the way of treatment, is never thoroughly examined on account of the inordinate length of time which the processes of hardening, cutting, staining, and mounting will require. Fresh sections of tissues are difficult to prepare and often decidedly unsatisfactory. Of the various fluids in use for hardening animal tissues before section, two are commonly employed—namely, alcohol

<sup>\*</sup> These stations are located at: Delaware Breakwater; Reedy Island, Delaware River; Cape Charles, Virginia; Blackbeard Island, Sapelo Sound, Georgia; Brunswick, Ga.; Dry Tortugas, Fla.; Ship Island, Gulf of Mexico, off the coast of Mississippi; San Diego, Cal.; Angel Island, San Francisco Bay, California; Port Townsend, Wash.

and chromic acid. Absolute alcohol hardens most tissues in some four or five days, but has the great disadvantage of being apt to render them brittle or to harden them very unequally. Methylated spirit will take a fortnight or more to produce a satisfactory result. Chromic acid is generally used as potassium bichromate in solution with some sodium sulphate in the wellknown Müller's fluid. Wherever the sulphate penetrates-and it has great power in this direction-the chromic salt will follow and harden the tissue extremely well; but the process requires an inconvenient length of time-in fact, often as long as six weeks, and with many renewals of the reagents. Pure chromic acid, or chromic acid with spirit, hardens in about a week, but again is liable to make the tissue brittle. Perchloride of mercury interferes much with staining, though it hardens rapidly. Thus any reagent which tends to shorten this period of time, and yet produce satisfactory results, is to be welcomed.

"Experimenting in some other ways with formic aldehyde, I was much struck by its extremely powerful and rapid hardening effect. I therefore determined to test its action upon tissues, especially very soft varieties of normal and pathological structures, just indeed those most difficult to prepare for section. Normal cerebellum, testis, lung, thymus gland, and ciliated epithelium of the trachea all hardened well in three days when immersed in a twenty-per-cent. solution of the aldehyde, though for the testis and lung a forty-per-cent, strength is the better. None of the tissues became brittle, but all were easily cut after soaking in gum with an ether-freezing microtome, and all stained well with logwood and some with logwood and eosin. None of the cells of the various specimens were altered in shape or character.

"Of pathological tissues, a very soft round-celled sarcoma from the head, an adenoma of the thyreoid gland, and some emphysematous lung were treated with a forty-per-cent solution, and all were sufficiently firm in forty-eight hours for cutting; and again all the sections took the ordinary stains well. The lung tissue was, however, somewhat brittle. Compact growths, such as scirrhus or renal tissue, require only a ten-percent. solution for twenty-four hours.

"I am thus led to think formic aldehyde in forty-per-cent. solution for very soft tissues, in twenty-per-cent. for firmer, and ten-per-cent. for quite firm material, acts as a most rapid and satisfactory hardening reagent. It does not render any tissue brittle in the way spirit does, and in no way prevents a stain acting well on the sections. It is therefore a useful adjunct in pathological and histological work."

Paralysis following Diphtheria of the Genitals only .-In the Lancet for May 26th Dr. W. Gayton relates the case of an unusually well developed and nourished girl, four years old, who was admitted to the Northwestern Fever Hospital on October 28, 1893. Her condition was as follows: The skin of the groins, labia, and vulva was excoriated, owing to a very offensive, copious vaginal discharge. The whole of the parts were found to be extremely swollen and covered with a membranous exudation of the true diphtheritic character, which had also crept along the vaginal cavity as far as could be seen. No urine, it was reported, had been passed for two days (?), and the bladder dullness extended a considerable distance above the pubes. As exquisite tenderness was present, preventing any attempt at instrumental interference, the patient was anæsthetized and a catheter passed. Some urine escaped while the patient was under the anæsthetic, and a little was drawn off and showed a trace of albumin. The temperature was 96° F. only, the countenance very pallid, and the pulse feeble and slow. The inflammation of the vulva, it was stated, had existed for a fortnight, but the throat was not, and had not been, previously affected in

the slightest degree by membrane. By the frequent application of a perchloride-of-mercury solution, with the administration of iron and brandy and a generous diet, steady improvement ensued, so that by the 19th of the following month the parts were nearly healed and the vaginal discharge had ceased; the albumin, however, continued, and the pulse and temperature kept subnormal. On the 23d marked strabismus was observed, also palate paralysis, with regurgitation of fluids through the nostrils and an irritating noiseless cough. By the 26th the muscles of visual accommodation were impaired, the albumin persisting, slight vaginal discharge returned, but the genitals were quite free from membranous exudation and presented a perfectly healthy appearance. On the 30th the paralysis was more general, the typical apathetic look and bearing being very pronounced. On December 5th there was great difficulty in swallowing, the muscles of deglutition being now involved in the general paresis, with an almost constant impotent cough. Much headache was complained of, there was rapidity of pulse, and there was more albumin, but there was less secretion of urine. Feeding by tube was resorted to, but death took place next day, due, apparently, to the direct toxic action of the diphtheritic poison on the bulbar centers, which, says the author, is unfortunately so apt to occur with those children who become apathetic and have a nasal quality of voice, irregular sighing respiration, loose, almost noiseless, cough, with mucous accumulation and a rapid pulse.

The Treatment of Tapeworm in Children.—In the Journal des praticiens for May 26th Dr. Descroizilles relates the case of a girl, twelve years old, who had tapeworm. She complained of pains in the head, and her appetite was capricious. Diarrhœa and constipation alternated, and traces of tapeworm were seen in the stools. The author prescribed eight grains of calomel, and three days later the same quantity of santonica. This was followed by the expulsion of fragments of the tapeworm, thus confirming his diagnosis. Dr. Descroizilles hesitated to interfere directly by a radical treatment, but owing to the persistence of the parents determined, meanwhile, on an immediate intervention, and the following method was employed: 1. For two or three days a special diet, such as fish or vegetable soup, eggs, milk, and a moderate quantity of bread. 2. During the last twenty-four hours nothing but milk. 3. On the day before the attempt at expulsion, toward evening, a laxative enema to be given. A second enema also to be given three hours before the administration of the following remedy: 4. Ethereal extract of male fern, two drachms; calomel, seven grains; peppermint water, two drachms and a half; gum arabic. seventy-five grains; syrup, five drachms; distilled water, a sufficient quantity to make a mixture of two ounces. A tablespoonful to be taken every ten minutes. 5. Several hours later an enema of castor oil, of from six to seven drachms, to be given.

Dr. Descroizilles prefers the ethereal oil of male fern to quince seeds, kousso, pomegranate, and other preparations of male fern. He prefers it also to pelletierine, the action of which is less regular. It is the best remedy for children if it is given in capsules or in gelatin and sugar.

The author is disposed to try a formula given by M. Duhourcau, who combined green ethereal extract of male fern, chloroform, castor oil, and croton oil. The chloroform renders the worm torpid, the extract of male fern is a tæniacide, and the castor oil acts as a purgative. The author thinks it is an ingenious combination which responds to the various indications in the rational treatment of tapeworm.

Chlorine as a Local Stimulant.—At a meeting of the Clinical Society of London held on May 25th, a report of which appears in the Lancet for June 2d, Dr. Diver read a paper on

the use of chlorine gas in the treatment of chronic ulcers of the leg, founded on the cases of two old women in the lower ranks of life. The gas used was formed by pouring about two drachms of potassium chlorate, with a drachm or more of hydrochloric acid, into a pickle jar or a marmalade jar, the outside of which was covered with brown paper. Then a disc of white paper was introduced, and over the paper a sufficiency of absorbent wool was placed. Then a large cork was fitted to the neck of the jar. The wool, yellowish-green on the surface when first exposed to view, was then placed over the ulcer in each case and quickly covered with gutta-percha tissue. Over this the patient was allowed to employ whatever she had been accustomed to in the way of bandaging or covering. Rest was not enjoined. The gas employed, said Dr. Diver, was probably chiefly chlorine with some peroxide of chlorine. At the time of the beginning of the treatment the first patient had a varicose ulcer on each leg, between the calf and the ankle. Both ulcers improved steadily under the treatment, and in eight weeks the one on the left leg, having been dressed three times a week, was well. This ulcer had not before been healed for twenty-five years, and at the time the treatment was begun it was over two inches long and nearly two inches wide. The ulcer on the other leg had nearly healed, but its progress had been impeded by accidental circumstances. In the second case there was a large ring-shaped ulcer which had followed the bite of a cat some twenty years before. It extended from a little above the ankle nearly to the middle of the calf, and was very deep. It was treated in exactly the same way, and soon its ashy surface showed granulations which went on increasing until, after six weeks' treatment, they reached the level of the skin. Since then the ulcer had maintained its granulations, its extent had been narrowed very considerably, and it was still steadily improving. The patients were shown, together with drawings of the ulcer in the second patient, illustrating its appearance at the time the treatment was begun and subsequently.

The Alumni Associations of Columbia College in the City of New York.—The following circular has been addressed to the members:

The University Council of Columbia College has constituted a Standing Committee on Aid for Students, consisting at present of the following members:

Professor E. R. A. Seligman (Faculty of Political Science), chairman; Professor F. M. Burdick (Faculty of Law); Professor G. S. Huntington (Faculty of Medicine); Professor F. R. Hutton (Faculty of Mines); Professor J. F. Kemp (Faculty of Pure Science); Professor E. D. Perry (Faculties of Arts and Philosophy).

It is the design of the committee to put needy students, especially those coming from elsewhere than New York or the immediate vicinity, in the way of earning enough for their partial or complete support, or if possible to extend assistance to them in other ways, while they are pursuing their studies here. It is believed that many opportunities might be offered to students of this class if the fact of their desire to obtain such employment were generally known. Some of the methods that have been suggested are: private tutoring, translating, copying of various sorts, teaching in evening schools.

We are striving to make New York a real university center in this country, as are Paris in France and Berlin in Germany, and we are already receiving assurances of co-operation from many quarters, both public and private, in this city.

Your co-operation with the work of the committee, by suggestions or in any other way, is earnestly requested and will be most gratefully accepted. Communications may be sent to any member of the committee.

The Employment of Cocaine as an Antigalactic,—In the Lyon medical for May 20th Dr. Joire writes that he has observed that cocaine used in cases of painful cracking of the nipple diminishes the lacteal secretion, and that this fact suggested to him the idea of employing it in a regular manner in cases where the patients desired complete suppression of this secretion. The author employs the following solution: Cocaine hydrochloride, seventy-five grains; distilled water, an ounce and a half; glycerin, an ounce and a half. This solution is applied with a soft brush five or six times a day, and suppression of the secretion is obtained in from two to six days. There is never any inconvenience from the use of this solution on account of the surface painted being so limited. Cocaine, by producing anæsthesia of the nipple, hinders its erection, which, according to M. Joire, favors the lacteal secretion.

Rhythmical Tractions on the Tongue in the Treatment of Asphyxia from Hanging.—M. Laborde recently read a paper with this title before the Académie de médecine, the proceedings of which are reported in the *Progrès médical* for May 12th. The author said that, among all the different forms of asphyxia in which this method had been employed successfully, there was one that had not been mentioned, and that was asphyxia from hanging, in which, however, experiments had shown that the procedure was quite favorable. The following case had been observed by M. Luys, and was presented by M. Laborde: A man, thirty-three years old, had been resuscitated by this method after hanging for several minutes, and when all other means had failed. The rhythmical tractions were kept up for at least ten minutes.

A Case of Obstinate Membranous Enteritis.—La Preshe médicale for May 19th gives the following treatment, which was successfully used in the case of a young woman: 1. Every morning an energetic general friction with a glove saturated with oil of turpentine. 2. Twice a week a hot bath in which a pound of sea salt and nine ounces and a half of sodium carbonate have been dissolved. 3. Each morning, taken slowly, in a recumbent posture, an enema, as hot as possible, of nine ounces and a half of boiled water in which half a drachm of borax has been dissolved. 4. Every day, before the midday meal, nine grains of quinine sulphate. 5. The exclusive use of beer, milk, and Evian water.

The Woman's Medical College of Baltimore.—Dr. Eugene F. Cordell, of Baltimore, informs us that Dr. Charles E. Simon has been appointed professor of physiology and histology; Dr. Charles O'Donovan, professor of diseases of children; Dr. Pearce Kintzing, professor of chemistry; Mr. Ralph Robinson, LL. B., lecturer on medical jurisprudence; Dr. Berwick B. Smith, lecturer on pathology; and Dr. Claribel Cone, lecturer on hygiene. The session is to be lengthened to eight months, and the three-year course has been required for graduation since 1884.

Phosphorus Butter.—The British Medical Journal credits M. Comby with the following formula, a modification of Trousseau's, for the preparation of an iodo-phosphorated butter which may be used as a substitute for cod-liver oil in hot weather: Fresh butter, seventeen ounces and a half; potassium iodide, four grains; potassium bromide, fifteen grains; sodium chloride, two drachms; phosphorus, one seventh of a grain. About a third of an ounce is to be taken daily, spread on bread.

An Application for Insect Bites.—The Presse médicale gives the following formula: Strong ammonia water, thirty parts; collodion, ten parts; salicylic acid, one part. A drop of the solution to be applied to each bite.

# APPENDICITIS STRICTLY A SURGICAL LESION.

BY JOHN A. WYETH, M.D.

It is not my intention to go into the pathology, symptoms, diagnosis, or operative technique of appendicitis. There is practically nothing to be added to such contributions to the literature of this subject as the paper of Professor William H. Welch in the Transactions of the Congress of American Physicians and Surgeons, vol. ii, page 5; The Importance to the Surgeon of Familiarity with the Bacillus Coli Communis, by Professor Roswell Park, in Annals of Surgery for September, 1893; a classical paper, Observations upon Appendicitis, by Dr. George Ryerson Fowler, in the same paper for January, February, March, and April, 1894; Remarks upon Appendicitis, by Maurice H. Richardson, M. D., in the American Journal of the Medical Sciences, January, 1894; Remarks on Appendicitis, by Professor Christian Fenger, in the American Journal of Obstetrics, August, 1893; Ueber Aetiologie und Pathogenese der Peritonitis durch Perforation, by Barbacci, in Centralblatt für allgemeine Pathologie, 1893; and several practical and excellent articles by the late Professor Sands, and by McBurney, Fitz, Weir, Baruch, Keen, Bull, Bryant, Senn, and others.

Suffice it to say that the danger to life which makes appendicitis strictly a surgical lesion is peritonitis, and this may occur not only with, but without perforation. Through any portion of the walls of the appendix, the vitality of which is materially impaired by ulceration or gangrene and yet not perforated, septic micro-organisms or ptomaines from the alimentary canal may pass and thus precipitate septic peritonitis, local or general. That gases also pass through is evident from the peculiar fæcal or intestinal odor imparted to the contents of the abscess or cavity of the peritonæum, when the most careful search shows no perforation is present.

When perforation exists, the septic process is rapid and, unless encapsulated by the accident of peritoneal adhesions, soon induces a fatal termination.

In all the range of the materia medica there is not an agent which can prevent peritoneal infection from a diseased appendix, nor is there an agent which exerts a curative influence over this disease when once established. In the presence of this most grave malady the physician is powerless save in the allaying of pain, the assurance of quiet and the conservation of the patient's strength by proper nourishment. If the disease is mild in type, the inflammatory process limited, and resolution occurs, he congratulates himself, and is to be congratulated for his luck rather than judgment. If perforation and general infection or abscess, or obstruction by adhesions occur, he has recourse to surgery at a time when the hand, which earlier might have interfered for the patient's safety, is often invoked too late.

In my entire experience with this lesion I have yet to see a death which could not properly be ascribed to delay in timely and skillful surgical interference. With all respect to the diagnostician, I do not believe it is within the scope of human judgment to determine from the symptoms whether or not perforation or gangrene is about to occur, whether peritonitis with or without perforation is being circumscribed by adhesion or spreading to general infection. Every surgeon of experience is familiar with such cases. I do not mean to say that by a careful study of the symptoms these conditions may not be made out in a fair proportion of cases, but I do mean to say that, as at present treated by our profession, the rate of mortality is greater than it should be, and I do know from my own experience that prompt surgical treatment will give a better ratio of recovery.

In a short paper based on eleven cases treated in the month of September, 1892, before the Surgical Section of this Academy and in a subsequent report, I maintained this position, and if you will bear with me in a condensed recital of more recent cases I will still further strengthen the conclusion that every case of appendicitis from the first dawn of a symptom of the disease should be treated by a surgeon, with the regular medical attendant.

On February 6, 1894, I was called to Astoria in consultation with Dr. H. O. Fitch and Dr. J. D. Trask. The patient, A. B., aged twenty-one years, was an athletic, robust man, with no previous disease. He had had two or three attacks of "cramps" in the bowel within the last two years, but there was no pain in the right iliac region, no tenderness, or no muscular resistance. The pain in these attacks was felt at the umbilious and a small dose of morphine had in each instance relieved him, and on no occasion was he kept from his business.

On Monday, February 5th, he had dined heartily in New York city, reached his home by twelve midnight, and retired as well as ever in his life. At 2 a. m. he was awakened by a pain in the right iliac fossa and sent for Dr. Fitch, who saw him at 7 a. m. This time the pain was well marked at the appendix. The temperature was 101.5° F.

I saw the patient at 2.30 p. m. He was lying on his back with the legs in full extension. The temperature was not quite 102° F. There was some muscular resistance which yielded when the muscles were relaxed at will; pain not severe on pressure. He had not vomited and no morphine had been administered. Deep pressure recognized a small resisting body at the location of the appendix. There was not a symptom in the case which might not have excused operative interference with the hope of resolution. Knowing as I did, with such a robust subject, that exploration was not dangerous, and knowing, as I have had sad reasons for remembering, of many cases in which the patient perished from timidity and delay, I advised operation, and Dr. Fitch and Dr. Trask promptly coincided.

The appendix was found greatly distended with soft semisolid ingesta, coiled on itself, as shown in this picture, and deeply mottled in its whole extent and evidently becoming rapidly gangrenous. It was not perforated. I tested this by forcing water into it after removal, and, under pressure, it was impermeable. On the contiguous surfaces of the colon and ileum yellow films of peritoneal lymph with a covering of creamy pus was seen. The first ligature applied to the appendix broke through the gangrenous wall, and the final ligature was tied at the line of the excum. I do not give the operative technique, for it is too well known to require repetition here. The recovery was uninterrupted.

α, α, the appendix imprisoned in a mass of organized lymph.

In this case had operation been delayed, rupture of the appendix was inevitable within a few hours, and there was no chance of encapsulation by adhesions. Death would surely have followed.

It so happened that on the following day I was called to see a boy, five years old, hitherto healthy and robust, who on Sunday, February 4th, had complained of a pain in the stomach. During that night he vomited, had a chill, and at 5 A. M. Monday, high fever. His physician was called and at 9 A. M. found him with temperature of 100°, abdominal muscles resistant, and pain chiefly about the umbilical region. Opium and bismuth were prescribed, and later oil, which moved the bowels. The symptoms increased in severity through that night and on the next day, and on February 7th at 11 A. M., on the fourth day after the onslaught of the appendicitis, I was called to operate. The pulse was rapid and weak; temperature, 103°. Abdomen greatly distended and very painful to pressure. The facies abdominalis was present, and altogether the case seemed hopeless; nevertheless, I opened the abdomen only to find the peritoneal cavity hyperdistended with fœtid pus saturated with intestinal contents. The appendix was ruptured through an ulcerative patch, out of which ingested matter was oozing. This was removed, a second incision made in the median line to facilitate thorough washing out of the cavity with warm boricacid water, and drainage out of the deepest portion of the pelvis, as well as through the incision over the appendix. The child rallied fairly well. On the day following, obstructions due to paralysis of the intestine from peritonitis caused such distention that an artificial opening was made in the ileum at the wound in the iliac fossa. A large amount of gas and some ingested matter escaped and the distention was relieved. Death occurred on February 10th from septic infection.

These are two illustrative cases. One was saved by prompt operation, the other perished from delay. The death-rate in appendicitis as at present treated is about eighteen in a hundred. Richardson, of Boston, reports one hundred and eighty-one cases, forty-three deaths, or twenty-four per cent. Murphy, of Chicago, one hundred and forty-one cases, sixteen deaths, or eleven per cent. At Mount Sinai Hospital in 1893 there were treated forty-two cases with seven deaths, or 15.5 per cent., this total of three hundred and sixty-four cases giving a mortality ratio

of eighteen per cent. I venture to say that if a competent surgeon were called within the first twelve hours from the first symptoms of appendicitis, this death-rate would be brought down to five per cent. or less, and I believe that if every case were properly explored and, if necessary, operated upon within the first twenty-four hours of the first symptom, the death-rate would not be two per cent. In Bull's statistics of three hundred and forty-one cases of chronic relapsing appendicitis the fatal cases were seven—not quite two per cent. Granting his conclusion, that this ratio would be increased to five per cent. if all cases were made public, the conclusion must also be accepted that early operation in acute cases would be made under more favorable conditions and would yield a lower death-rate.

It may be that the surgeon who leads trumps when he is in doubt might open into the abdomen of a certain small proportion of cases in which the appendix was not diseased, but such an error is in the direction of safety. Careful and skillful exploration of the peritoneal cavity is not dangerous. The danger of ventral hernia in the line of incision is insignificant when the incision is properly made and the recumbent posture maintained for six weeks while the wound is firmly uniting.

Again, failure to operate early in the history of an appendicitis invites disaster in other forms than death. Fæcal fistula from the ruptured appendix or from the colon, which breaks down from the pressure of the abscess or inflammatory tumor; adhesions and recurrent attacks of appendicitis, compelling operation under difficult conditions; and intestinal obstruction are of frequent occurrence.

On February 13th, within a few days of the two cases first detailed, I was consulted by F. B. S., thirty years old, who came to me with his physician, Dr. Hancock, of Wisconsin. This patient had acute appendicitis in February, 1893. A large abscess was opened on the ninth day, and one week later fæcal matter escaped and had continued to escape to this date. He was subjected to operation for closure of the fistula. Had this patient been operated on within twenty-four hours of his illness, no such disaster would have followed.

On January 25, 1894, this specimen was removed with considerable difficulty from A. W., of Kinderhook, who was brought to me by Dr. Kittel of that town. He was thirty-one years old, and in June, 1893, had a slight attack of appendicitis; a recurrence in August, lasting for thirteen days; a third seizure in September, and in December a very severe attack which put him to bed for three weeks. At this time there was a well-marked tumor in the iliac fossa and high febrile movement. The appendix was found firmly adherent to the side of the rectum and bladder, the execum being greatly displaced and evidently drawn down by the weight of the inflammatory tumor and subsequent contractions. This patient made a good recovery, but he should have been operated upon in the first attack, when the danger and difficulty would have been insignificant.

On March 1st of this year I removed this most instructive specimen from H. T., a man thirty-four years old, brought to me by Dr. Abruzzo and Dr. Bettini, of this city. A well-defined tumor was located in the right iliac fossa. Seven weeks before, he had noticed it after an attack of cramps in the bowels. It was not sensitive to pressure, nor was there any rigidity of the abdominal muscles. The temperature was normal.

He said the tumor was getting larger all the time. On exposing the cocum it was covered at its end by a tumor composed of organized lymph. Dissecting down to a depth of about three fourths of an inch into the mass, the appendix was found to form the center of the tumor. It showed the traces of an inflammatory process and looked withered up from the pressure of the enveloping lymph which had contracted around it. The tumor, with its appendix, was dissected from the cœcum, and the contiguous ileum and stump buried by inclosing sutures. At this juncture I felt a number of hard foreign bodies in the ileum which at once told me that there was a stricture at or near the ileo-cæcal valve which would allow semi-liquid intestinal contents to pass out but arrested solid matter. I opened the ileum, introduced my index finger into the gut, and found the tip could scarcely be engaged in the opening, which was not more than a fourth of an inch in diameter. By gradual divulsion the finger was forced through to its largest diameter and the wound in the intestine closed by ten Lembert sutures. About two weeks later a lot of orange seeds were discharged through the anus, some of which are shown with the specimen. The patient recovered.

On April 2d this specimen was removed from a lady about thirty-five years old, who eight days before had the first symptom of pain at the appendix. Three months before, she had experienced slight pain in this same region, which persisted mildly for three or four days and went away. In this last attack, however, the pain did not cease, but was not severe. On the fourth day, with a normal temperature, the abdomen began to swell, and for two days before I saw her she was vomiting at frequent intervals, and for twenty-four hours intestinal contents. Recognizing intestinal obstruction, I cut down upon the appendix and found it small-about a fourth of an inch thick, three inches long and perfectly healthy, save at the tip, where a pinhole perforation existed. This had produced a general septic peritonitis and an adhesion of a loop of small intestine, with complete obstruction about four feet from the ileo-cæcal junction. The appendix was tied off and the obstruction relieved. The intestine was gangrenous at the point of occlusion and burst after it was lifted out of the peritoneal cavity. It was closed by suture and the weak spot attached to the margin of the abdominal incision. She died from sepsis thirty-six hours after the operation. If this patient had been operated upon within twenty-four hours of her second attack, she would have escaped the disaster which followed.

These cases are taken as they have come in my practice. They are the common experience of many surgeons and they point unmistakably to the wisdom of early operative interference. Given a surgeon of experience, a clean operator, who, with the minimum of traumatism to the intestines or contiguous viscera, can remove a diseased appendix, and it would be better for exploratory laparotomy to be done in every instance within the first twenty-four hours of the disease.

On the contrary, were I the subject of an attack and were I not sure of my surgeon, I would keep flat on my back, quiet peristalsis and voluntary motion with morphine, and take the chances of resolution, encapsulation by adhesion, or rupture into the intestines. If there is one particular operation an inexperienced man should in all conscience avoid, it is this.

St. John's Riverside Hospital, Yonkers.—The new hospital was dedicated on Thursday, the 28th inst.

#### THE

EPITHELIO-GENETIC ORIGIN OF CARCINOMA.\*

By JOSEPH McFARLAND, M. D..

DEMONSTRATOR OF PATHOLOGICAL HISTOLOGY, UNIVERSITY OF PENNSYLVANIA.

The title which has been chosen for this paper is probably a bad one in that it is ambiguous and may be construed to mean a discussion of the old question, Does carcinoma arise from epithelium alone, or can it also originate from the connective tissues? Almost all pathologists now adhere to the former view, so that a further discussion would be useless. The title intends to convey the idea that carcinoma arises from epithelium by abnormal growth of that tissue, without any parasitic influence, in which sense the carcinoma is epithelio- not protozoo-genetic.

The parasitic theory of carcinoma is not new, yet it is not old, and the majority of the members of this congress have seen its development as the science of bacteriology developed, watched its acme under the feverish enthusiasm of Scheuerlen, Schill, and Kubassoff, and marked its rapid defervescence under the radical treatment of Senger, Baumgarten, and Rosenthal. After this a year passed quietly by, then the theory suffered a relapse in a somewhat modified form at the hands of Malassez, Albarran, Darier, and many others whose conclusions are that carcinoma is a parasitic disease, produced by an animal parasite closely related to the coccidia of the rabbit.

The discussion of this newer theory of the ætiology of carcinoma naturally divides itself into two principal parts:

- I. Are animal parasites present in carcinoma?
- II. If present, are they of ætiological significance?
- I. Are Animal Parasites present in Carcinoma?—To do justice to this very important question it seemed necessary to combine a careful review of the literature with my own researches upon the subject, but the prosecution of this idea gave birth to so voluminous a manuscript that all hope of embodying it here was given up and it was separately published (University Med. Mag., September, 1893).

Given very briefly, the history of these animal parasites is as follows: The Coccidium oviforme had long been known to infest the liver of the rabbit. Malassez observed similar bodies in the epithelium of Paget's disease. Thoma (Fortschritte der Med., 1889, vii, p. 413) found similar bodies in carcinoma, and these observations were elaborated by Sjöbring (Fortschritte der Med., 1890, viii, p. 529), Foá (Centribl. f. Bakt. u. Parasitenk., 1892, vol. ii, No. 6), Podwyssozki (Centribl. f. Bakt. u. Parasitenk., 1892, vol. xi, Nos. 16 and 17), Sawtschenko (ibid., 1892, xii, No. 1), Soudakewitch (Ann. de l'Institut Pasteur, 1892, vi, pp. 145 and 545), Ruffer and Walker (Journal of Path. and Bact., 1892, vol. i, No. 2), and others, and the described bodies finally pronounced to be protozoa and the cause of carcinoma.

My own observations coincided with those of the preceding investigators in the discovery of the bodies in question, some of which were found in nearly every one of the forty carcinomata which I studied. The bodies called

<sup>\*</sup> Read before the First Pan-American Medical Congress.

parasites I generally found in the epithelial cells, in one instance in the nucleus, but in all others in the protoplasm. They are spherical or slightly oval in shape, smooth in outline, not infrequently seeming to be surrounded by a double capsule. Sometimes they are homogeneous, sometimes homogeneous containing a more or less distinct nucleus, sometimes are granular throughout. The size varies from an almost imperceptibly small sphere to one so large as to distend the cell and compromise the shape of the nucleus by the pressure exerted. The majority are very uniform, however, being of about two to two times and a half the size of the nuclei of the epithelial cells. The separation between the inclosed body and the protoplasm is always sharp, and sometimes a space exists between the surface of the inclosure and the cavity in the protoplasm as if the foreign body occupied a vacuole. When nuclei are present they are a trifle indistinct in outline, sometimes appearing simply as a collection of granules near the center of an otherwise homogeneous body. Occasionally forms were found in which the granules arranged themselves in a cruciform figure; again, others in which, instead of the crosses and stars being made up of granules, they were caused by the absence of granules which had collected elsewhere in the cell. In none of the bodies were radiations observed.

Methods of staining, upon which so much emphasis has been placed, seem to be variable and unreliable in action. The best results were secured with hæmatoxylon and eosin, the granules and nuclei taking on a bluish tinge, while the homogeneous material tinges very slightly with the eosin. Biondi's method is less constant, and in my hands less clear in its results, and after a few trials I rejected it.

The best results very naturally accrue from the best methods of preservation, probably for no other reason than that the cells are all better preserved. The bodies, however, are distinctly visible in specimens preserved in Müller's fluid, alcohol, or other common preservatives.

The epithelial cells occupied by the bodies are not normal in other respects, but generally have distorted, shrunken nuclei and often a vacuolated protoplasm. Walker and Plimmer (Journal of Path. and Bact., 1893, vol. i, No. 4), who see these bodies originate in the nuclei, escape into the protoplasm, and develop there, also see great regenerative powers in the nuclei, which rapidly heal and appear normal. My observations differ from these.

Upon the appearances presented by the bodies observers are nearly all in accord, but the inferences drawn from these data differ most widely.

What are these seemingly cellular entities so common in cancer cells? Our judgment upon this matter can not be too conservative, and in forming it we must clearly understand the reasons given for regarding the bodies as parasites.

The first reason given is a diagnosis by exclusion. If the bodies are not parasites, what are they? To answer affirmatively is by no means a necessary sequence, for there are many things of which we are ignorant, perhaps more in pathology than elsewhere, and not to know what the things are does not make them parasites.

The second argument is the supposed homology between these so-called parasites and the coccidia of the rabbit. Now, when this homology is submitted to a careful analysis, it proves to be no homology at all. It is not morphological, for between these spherical homogeneous cellular inclosures and the large oval Coccidium oviforme there is not a particle of resemblance. It is not developmental, for we know of the Coccidium oviforme that, when it is removed from the body and subjected to proper temperature and moisture, the oval cells divide into four smaller cells, each of which contains delicate falciform embryos, and that these, when taken into the body in food or water, protected by the surrounding capsule, pass through the stomach and escape into the intestine, where the capsule dissolves and allows the amœboid embryos to enter the intestinal and biliary epithelium. Of the organisms found in cancer no such cycle has been seen. Neither is the homology pathological, for the changes in the liver produced by the coccidia are in no way similar to cancer. The lesion produced by these organisms seems entirely the result of a chronic inflammation of the bile ducts, and the irregular epithelial growth that results is more like the harmless tumor known as adenocystoma papilliferum than like cancer. In the absence of any real morphological, embryological, and pathological resemblances between these cellular inclosures and the coccidia, we find the absence of all scientific grounds for the assumption that we are dealing with positive, independent, animal bodies.

The arguments against the parasitic nature of the inclosures are, however, much more weighty, for no one has succeeded in finding similar bodies elsewhere than in cancer cells; no one has succeeded in cultivating them outside of their customary environment, or observing their growth in that environment. They do not reproduce themselves when inoculated into animals, nor do they in any way exhibit any manifestations that could not be otherwise accounted for than by the assumption that they are animals.

But, if they are not parasites, what are they? Every investigator who describes these things is careful to tell us how to distinguish between them and leucocytes; hence sees a distinct resemblance between them. The distinguishing feature given for this differentiation is almost invariably some staining reaction, and no less reliable method could be employed, for we all know how the health or degeneration of a cell causes its staining capacity to vary. My belief is that, instead of parasitic animal forms, we have to deal with a variety of things, of which leucocytes are among the most important. We all know how common leucocytes are in cancer, and all of us have perceived leucocytes, sometimes numbers of them, within the epithelial cells. If there be any truth in the doctrine of phagocytosis, it is natural that one or the other cell will suffer from this relationship. That epithelial cells are phagocytic can scarcely be doubted by those who have examined cases of brown induration of the lungs or catarrhal pneumonia. If the epithelial cells of carcinoma are phagocytic, it is natural that the smaller leucocytes shall be digested, and, if this takes place, what a variety of appearances partially digested leucocytes may present we can scarcely guess.

I believe that many of the so-called parasites are nothing more than partially digested leucocytes; others, of the homogeneous type, I conceive to be the result of the globular hyaline degeneration; while still others, together with what some have described as "empty capsules," must be regarded as simple vacuoles.

But, and this is the exception which makes a second part of this paper necessary, there have been described by Soudakewitch and Pfeiffer (Die Protozoa als Krankheitserreger) certain forms so unlike the bodies which we have had under consideration, so unlike anything belonging to the human body, so much like the Gregarinida, so peculiar in their radiate structure and seemingly amæboid powers, that we can not but admit the possibility of the very rare occurrence of true protozoa in carcinoma. These bodies are large, and seem as frequently to lie between the cells as within them, and while even of these exceedingly rare forms nothing has been proved, yet their homologies of form are sufficient guarantee for us to consider thêm true animal forms, if for no other purpose than to stimulate a study of their ætiological importance.

II. If Animal Parasites are present in Carcinoma, are they of Ætiological Significance?—This question includes a second question of great importance. Is cancer an infectious disease? Much has been written upon this subject, and an attempt to refute each argument advanced would consume so much time and space that I shall suggest but three topics for discussion under this head.

a. Cancer can not be Transmitted from Individual to Individual by Inoculation.—This is the most forcible argument which can be advanced against the micro-organismal nature of the disease.

In 1840 Langenbeck (Schmidt's Jahrbücher, vol. xxv, p. 104) made a mixture of carcinomatous tissue and dog's serum, injecting the same into the vein of a dog. This dog subsequently developed carcinomatous nodules in the lung. The experiment seemed like a brilliant success, but Virchow (Krankhaften Geschwülste, Bd. i, p. 87) tells us that he examined the microscopic specimens of these tumors, and found "more the appearances of that form of spontaneous cancer which he had, himself, found in dogs than that of cancer elements as found in men." From this we may conclude that much doubt must be placed upon the results of Langenbeck's work.

Alibert, it is said, inoculated himself and his pupils with cancer juices, but produced no cancers.

Follin and Lebert (Traité pratique des maladies cancéreuses, Paris, 1851), after fourteen days, found distinct cancer formations in the heart and liver of a dog into whose jugular vein juices from a mammary carcinoma had been injected. The experiment is of little value, because no microscopical examinations of the supposed cancerous tissue were made.

Goujon (Jour. de l'anat. et de phys., 1867) operated upon dogs, and was successful in the production of nodular formations where carcinomatous tissue had been inoculated. The microscope was not used to confirm the appearances.

Shattock and Ballance (Trans. of the Path. Soc. of Lond.,

1887, vol. xxxviii, p. 412), in a paper upon Cultivation Experiments with New Growths and Normal Tissues, together with Remarks upon the Parasitic Theory of Cancer, report numerous cultivation experiments with cancerous tissues, all of which were negative.

Wehr (Verhandl. d. deutsche Gesellschaft für Chirurgie, 1888, vol. xviii, pt. ii, p. 86) inoculated twenty-six dogs with fragments of five vaginal carcinomata and two carcinomata of the penis. The dogs were killed in three to four weeks, and in some of them distinct and large carcinoma nodules were found. It is not improbable that these were fibrous rather than cancerous. No microscopical examination of them was ever made.

Hahn (Berlin. klin. Wochenschrift, 1888) transplanted nodules of carcinomatous tissue excised from cancer patients to remote areas in the same individual, and found that the grafts increased in size and invaded the surrounding tissue. This, however, is no more than an artificial metastasis.

Senger (Berl. klin. Wochenschrift, 1888, vol. xiv, p. 234) failed in all his attempts to produce cancer by inoculation

Hanau (Verhandl. d. deutsche Gesellschaft für Chirurgie, 1889, vol. xviii, pt. ii, p. 276) made inoculations from one animal to another of the same species. Selecting a vaginal epithelioma occurring in a white rat, he introduced fragments into the tunica vaginalis testis of two old white rats. The first rat died after seven weeks with disseminated peritoneal carcinosis. The second was killed in eight weeks and was found to have but two tumors, one, of the size of a pea, at the tail of the epididymis, the other, very small, at the gubernaculum Hunteri. A third rat was inoculated from the second, and when killed three months after was found to have a widespread carcinosis. Hanau thinks the failures of other experimenters due to the miscellaneous selection of the animals used, and insists that the inoculations should always be from animal to animal of the same species.

Klebs (Deutsche med. Wochenschrift, 1890, vol. xvi, p. 709) wrote a thorough paper upon the various cancer inoculations, reporting many experiments upon rats, in all of
which he failed to produce a single tumor. The fragments of tissue introduced were found to be absorbed, no
other change than hyaline degeneration being observed in
them.

Cornil (Séance de l'Acad. de méd., Paris, 1891, June 23d) in numerous experiments failed to produce cancer by inoculation.

Frank (Deutsche med. Wochenschrift, 1891, No. 30) also failed to produce cancer by inoculation into animals.

Shattock and Ballance (Proc. of the Royal Soc. of Lond., 1891, p. 392; also Med. Press and Circ., Lond., 1891, September 9th) again entered the field, and in two papers report a lengthy and comprehensive study of cancer inoculations, in which eight monkeys, three rabbits, seven dogs, three sheep, and numerous other animals were used, in some of which whole scirrhous tumors were introduced into the abdominal cavity. In no case was a cancerous tumor produced, and the common sequence was the absorption of the

graft. These experimenters are of the opinion that the few successful inoculations reported are due to lack of thoroughness in the examination of the growths produced.

Senn (Surgical Bacteriology) mentions Billroth, Maas, Doutrelepont, Alberts, Senger, and others as having failed in their inoculations, and in his own inoculations, which were made upon dogs, cats, rabbits, and guinea-pigs, saw no other change than an invariable failure of the graft to increase in size.

Duplay and Cazin (Comptes rendus de la Soc. de biol., Paris, 1892, February 22d) in a series of twenty-two inoculations of cancerous tissue from man to rabbits, guineapigs, and dogs, attained no positive success, the fragments of tissue being absorbed. In a second series of experiments made in accordance with the idea of Hanau from dogs to dogs, no other changes than inflammation and subsequent absorption could be detected.

Fischel (Fortschritte der Med., 1892, No. 1) inoculated \*twenty-three rats, using as material three scirrhous cancers of the mamma, nine other carcinomata, and two sarcomata. All the inoculations were made within fifteen minutes after operation for the removal of the tumors, but not one of the experiments was a success.

It would be useless to add to this already long list, as its results are almost uniform. The work of Langenbeck has been rendered negative by the examinations of Virchow; that of Follin, Lebert, and Goujon is useless because no microscopical diagnosis accompanies it; and as that of Hahn is but an artificial metastasis, we are left nothing but the three inoculations of Hanau against hundreds of carefully made but unsuccessful attempts. The fact that Hanau's three experiments were all successful is a little suspicious, yet we will not reject them, because spontaneous cancer in animals is not rare, because cancer seems to run in families, and because cancer occurs in the old. We can conceive of old rats, with a family predisposition to cancer, developing squamous epithelioma in consequence of the irritation caused by the operation, independently of what tissue was introduced, and would admit this possibility existing in the case of Hanau's rats. The great weight of evidence, however, is such as to confirm the assertion with which we started out, that cancer can not be transmitted from one individual to another by inoculation.

There are numerous cases on record where carcinoma of the breast has subsequently given rise to carcinoma of the skin of an arm kept applied to it, where carcinoma of the lower lip has seemingly inoculated the upper lip, and where cancer of the penis has resulted from contact with a cancerous uterus. The first two illustrations amount to no more than the experiments of Hahn; the last is so extremely rare that it may have arisen spontaneously in every case. We must not omit to consider in relation to these cases that the discharges from cancers are unusually irritating and excoriating, and may in this way produce epitheliomatous growths on contiguous parts without the aid of any micro-organism.

b. Cancer is a Non-inflammatory Disease.—All the known infectious diseases except malaria are inflammatory

in type. Tuberculosis, lepra, syphilis, actinomycosis, and glanders are primarily inflammatory, secondarily degenerative. Typhoid fever is more purely inflammatory, while little degeneration occurs in anthrax and charbon symptomatique. Cancer is utterly unlike any of these, being a simple hyperplasia of epithelium extending into neighboring interstices.

I expect to be challenged on this ground and to have the objection raised that the coccidiosus of the rabbit is an infectious disease, but non-inflammatory, and that the resemblance of cancer to this disease is greater than that existing between cancer and other infectious diseases. To this I must reply that coccidiosus is an inflammatory disease, and that while it is at first a purely parasitic disease of the epithelial cells, it becomes a chronic inflammation of the mucous membrane with subsequent fibroid thickening, hypertrophy, and polyposis. That there is little homology between it and cancer has already been explained. The great difference between cancer and the infectious diseases can be more conveniently observed in the secondary than in the primary foci. In tubercle, for example, the secondary formations occur by the dissemination of the bacilli, and wherever a bacillus falls, chemiotaxis calls forth a body of leucocytes, connective-tissue cells, Wanderzellen, Schlummerzellen, and the like, which, together with the cells already present in the part, form the node. In cancer nothing like this takes place, and we can not conceive of the dissemination of "cancer germs" producing a secondary-especially the lymphatic-growths of this disease unless we believe in the transmutability of tissue which will permit the mesoblastic tissues to assume an epiblastic type, an opinion which few will support at present. The secondary growths of cancer depend upon the transportation and multiplication of cancer—i. e., epithelial cells. In their new habitat these foreign cells not infrequently conform to the normal mode of growth and take on their normal arrangement, so that even in nodules in lymph glands, fibrous tissue, etc., distinct alveoli may be observed. I can not conceive of epithelial cells, the hosts of irritating parasites, taking on such a rapid and healthy growth with so little variation from the normal.

c. Epithelium is Normally a Variable Tissue .- Our discussion of the subject would be far from complete should we neglect the peculiarities of the tissue in and from which carcinoma grows, which may have a most important bearing upon the development of the tumor. In youth epithelial tumors are rare, and the changes to which the tissue is subject are overshadowed by the pronounced growth of the connective tissues. As age advances a change in the body equilibrium occurs, in which the formative energy of the connective tissues ceases and distinct changes in the epithelium occur. Upon the face and hands of the aged the skin becomes thin and transparent, and there is a tendency for cellular proliferation to occur in local areas which appear as slightly elevated brownish spots. In some cases these areas send out irregular processes which descend into the deeper tissues and form the nucleus of a squamous epithelioma.

Bowlby (Brit. Med. Jour., 1892, vol. ii, p. 71) made a

systematic study of the mammary glands of persons at and beyond middle life, and found in all of them distinct changes in the form of proliferation of cells and alveoli. Beadles (ibid.) studied the non-cancerous portions of mammary glands amputated for cancer, and while in all of them he found, as Bowlby had done, proliferatoin of cells and aveoli, in some he found cellular infiltration and irregular cellular proliferation. The former of these changes I am inclined to attribute to age, the latter to the cancer.

In the Morton Lecture on Cancer and the Cancerous Diseases for 1892 (Brit. Med. Jour., 1892, vol. ii), G. Sims Woodhead mentions his observations upon a large number of tongues which he had the opportunity to study, and tells us that in advanced age the epithelium shows a distinct tendency to thicken and grow with the production of descending processes.

In addition to these changes, consequent upon advancing age, we find a great variety of appearances due to the operation of external agencies. Not to go into detail, let us simply consider the following: The hands of laborers, being exposed to friction, are subject to general thickening of the epidermis, with immense thickenings (callosities) at the most exposed portions. When a boot pinches the foot, a more circumscribed epidermal thickening (clavus) is produced. If a papilla or a small group of papillæ are irritated, a very different growth, involving the lower layers of the skin and more organoid in character (verruca), is produced. Upon delicate mucous surfaces chronic irritation produces polypi whose epithelium contains glands. Nor are the changes of the epithelium produced solely by factors operating upon it, but they may be brought about by changes in contiguous tissues. Councilman (Johns Hopkins Hospital Bulletin, vol. i, No. 2, p. 20, Jan., 1890) has shown that when, in consequence of chronic inflammation, granulation tissue is formed beneath the epidermis, the epithelium grows downward into the cutis, giving rise to a branching system of epithelium beneath the skin, probably occupying the lymphatic vessels, presenting a picture almost identical with squamous epithelioma and even containing epithelial pearls, but circumscribed in growth by the denser tissues beneath whose resisting powers at once check its progress.

Not long ago I secured from a gynæcologist a portion of a uterine cervix containing a rather minute laceration of long standing. In the process of repair the epithelium had descended to the bottom and almost filled up the fissure. At the outer part, where the tear was clean, the base of the epithelium was smooth, but at the termination of the tear, where it had separated neighboring muscular bundles but partly and left numerous crypts, the epithelium had grown with a branched arrangement fitting into these interstices, and only checked in growth by the greater resistance offered by the undisturbed tissues beyond. Had there been no healthy tissue in these two instances to check the descending processes in their growth, we must have had resulting epithelioma. Indeed, who can say what further extension might not have resulted in the course of time had the cervical tissue been suffered to remain in situ instead of being

the character of epithelium is such as to make a specific cause for its irregular development unnecessary. After all that has been said, it would be folly for us to accredit to the very occasional protozoa-like forms which have been mentioned more importance than that given to the accidentally present bacteria. Bacteria of various kinds are nearly always to be found in carcinoma, gaining access from the air, water, or food, either directly when the tumor occupies a surface, or through ducts, etc., when it is glandular in origin. It seems to me not improbable that, if bacteria can thus enter the abnormal tissue, protozoa of various kinds could do likewise. The suggestion of Andrews that the locations in which primary carcinomata occur favors the micro-organismal theory, concluding this from the study of seventy-eight hundred and eighty-one primary cancers (Pacific Rec. of Med. and Surg., San Francisco, 1889-'90, iv, 195), does not make it at all necessary that a specific organism must be present to cause cancer, for the primary cancers are most common upon the most exposed surfaces, as these bear the greatest mechanical, chemical, and physiological abuses.

I do not believe cancer to be due to any specific cause, but to have its origin from numerous and often co-operating causes, of which much still remains to be learned, but which will show us the principal factor in its production to be an inherent proliferative tendency in the epithelium itself, in which sense the origin of carcinoma may be said to be epithelio-genetic, not parasito-genetic.

# OZONE AND ITS USES IN MEDICINE.

BY WILLIAM J. MORTON, M. D.,

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM AND OF ELECTROTHERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

(Concluded from page 783.)

Historical.-It is to the labors of Schönbein (1839) that we owe the identification of ozone with oxygen, or rather nascent, electrified, or contracted oxygen, for, although unnamed, it was not unknown. Its peculiar "sulphurous" odor, perceptible after electrical discharge during heavy thunderstorms, had been perceived even in remote ages, as is evidenced by a reference made by Mohr (1) to some verses in the Iliad (viii, 135; xiv, 307) and in the Odyssey (xii, 417; xiv, 307).

Other authors who make mention of the peculiar odor accompanying discharges of lightning: Virgil, Æneid, ii 691-698. Seneca, Quastionum naturalium, ii, 21-53. Lucretius, De rerum natura, vi, 221. Lucanus, Pharsalia, vii, 221. Shakespeare, Cymbeline, Act v, Scene 4; King Lear, Act iii, Scene 2; Tempest, Act i, Scene 2; Pericles, Act iii, Scene 1, and other passages.

Benjamin Franklin (1749) ascribed the odor accompanying the working of an electrical machine and a discharge of lightning to decomposition produced by electricity (133).

The odor of ozone was also known to those experimenting with frictional electricity, but Martinus van Marum (2) In this brief fashion we have endeavored to show that was the first who made any investigations as to its nature. He experimented at Haarlem, in 1785, with the discharge of the electric spark through the atmosphere and also pure oxygen. He showed that when the electric spark is allowed to act for some time upon "dephlogisticated air" or oxygen, contained in a closed vessel over mercury, a considerable diminution of the gas took place, the mercury was oxidized, and the oxygen acquired an intense odor.

Cruikshank (3) also observed, in 1801, that a peculiar odor was perceptible during the electrolytic decomposition of water, which odor we now know arises from ozone.

From this period until 1839 nothing was observed in regard to the nature of ozone. On the 13th of March of this year, Schönbein (4) communicated to the Naturalists' Society at Bâle his experiments and observations of the characteristic phosphorus-like odor apparent during the electrolysis of water and the discharge of frictional electricity through the atmosphere. To the new substance he gave the name of ozone, from ὄζων, present participle of ὄζω (I smell). He considered it a substance similar to chlorine or bromine. On the 3d and 17th of April and on the 15th of May, 1844 (5) he again laid before the same society his researches, in a communication describing his discovery that ozone was produced during the slow oxidation of phosphorus in moist atmospheric air. He had, however, changed his views regarding it, believing it now to be a component part of nitrogen, and that this latter element was a combination of ozone and hydrogen.

The true nature of ozone was long a moot point and engrossed the attention of a number of investigators: De la Rive (6), Marignac (6), Frémy (7), Becquerel (7), Andrews (8), Tait (8), Von Babo (9), Fischer (10), Baumert (11), Soret (12), and others.

Odling (122), in 1861, suggested that ozone was a compound of oxygen with oxygen, the combination resulting in a contraction. He also conjectured that this contraction might proceed from a condensation of three volumes of oxygen into two volumes.

It was not until the year 1863 that a really precise definition of the constitution of ozone was promulgated. Soret (12) was the first to pronounce that ozone was really oxygen condensed to two thirds of its volume. His view was at first disputed by some investigators, but eventually confirmed by experiments conducted by himself and others. This opinion as to the constitution of ozone is, up to the present day, the one generally accepted. According to this acceptation, the ozone molecule consists of three atoms of oxygen, whereas the ordinary oxygen molecule contains but two atoms—

Baumann (13) styles the combinations of oxygen as follows:

- (O)2 Ordinary inactive oxygen,
- (O)<sub>3</sub> Ozone,
- (O), Active oxygen,

the latter being the most powerful oxidizing agent known. It combines with ordinary oxygen to form ozone.

Production of Ozone.—The great source of ozone is duce ozone (25).

found in the vast operations of Nature. Schönbein, on his discovery of this element, called attention to the fact that the peculiar "sulphurous" or "phosphorous" odor, perceptible in some localities, attendant upon a stroke of lightning, derived its origin from ozone. Andrews and Tait confirmed his views. It is an acknowledged fact that the silent discharge or interchange of opposite electricities from clouds to earth is a factor in the production of ozone; the intervening space being filled with the atmosphere, all the conditions are present necessary to the generation of this gas. The correctness of this theory is supported by the observations of Houzeau and others. Houzeau (14) found that during thunderstorms the air was particularly rich in ozone.

An examination of the atmosphere with the spectroscope reveals the presence of dark absorption lines in the yellow and red parts of the spectrum, always in the same place, proving the existence of ozone in the atmosphere. It has been proved that the color of ozone in a state of great density is blue; it therefore absorbs yellow and red light (133).

Meissner (15) was of opinion that ozone took an active part in the formation of clouds.

Ozone is also formed by the evaporation constantly taking place on the earth's surface; in fact, v. Gorup-Besanez (16) and Belluci (17) observed that it was developed whenever evaporation of water was in rapid process, and the more energetic the process of evaporation, the greater was the amount of ozone. The quantity was also-conditioned by the greater or less proportion of salts held in solution by the water. These investigators also found the air strongly ozonized in the neighborhood of waterfalls, irrigation systems, drying houses, near the sea, etc.

Scoutetten (18), Brame (19), and Kosmann (20) showed that plants exhale ozone, together with the oxygen which they give out during the daytime.

According to Ebermayer (21), ozone appears to be present in increased quantity in the vicinity of forests, especially those where trees of the pinus group predominate.

There are a great number of processes by means of which ozone may be produced mechanically, chemically, or by electricity.

Mechanically.—When air is forced through a narrow opening it is found to contain ozone (22).

The nobler metals in a finely divided state, such as gold and platinum, absorb a certain amount of oxygen and retain it in a condensed form, but yield it up to oxidizable bodies, with which ordinary oxygen shows no reaction; iodide of potassium and starch, showing an ozone reaction when brought into contact with black platinum, etc. (23).

Chemically.—Oxygen in contact with water or saline solutions in process of evaporation forms ozone (24).

Whenever oxygen enters into chemical combination it exists in the nascent state, with the accompanying formation of ozone. The moment that the oxygen is set free, some of its atoms, not as yet aggregated to molecules, unite with the already formed oxygen molecules and produce ozone (25). Schönbein (26) and Kingzett (27) noted the existence of ozone upon heating certain metallic oxides.

Phosphorus, oxidized at the ordinary temperature of the air (28), produces ozone, and the same result is obtained if a current of air is passed slowly through a tube filled with moist pieces of phosphorus. This method was for a long time the general one in use by most experimenters, until the invention of the apparatus by means of which the gas is obtained by the electric process.

Active oxygen is generated during every process where draught and low temperature promote its production and preservation. A strong current of cold air passing through the small flame of a Bunsen burner or a hydrogen flame is ozonized, and may be recognized by its peculiar odor (29).

Deville (123) produced ozone by means of a hot and cold tube. Oxygen heated to 1,400° and immediately cooled is converted into ozone. Similar conditions are present in ozone tubes, where the luminous discharge raises the temperature of the gas, which is then abruptly cooled by its contact with the rest of the gaseous mass in circulation.

Electrically.—Cruikshank (30) and later on Schönbein (30) showed that during the electrolysis of water the characteristic odor of ozone is perceptible.

The generation of ozone by the static electrical machine (31) is a fact well known to those interested in electric science. Both during the spark and brush discharge the odor of ozone is unmistakable.

The method now most extensively employed for the manufacture of ozone is that in which the silent discharge (32) or electrical effluvium is allowed to traverse a narrow dielectric space between two conductors, and, acting upon a stream of oxygen or atmospheric air, generates ozone in large quantities.

Ozone is also evolved by the electrolysis (124) of water, but only in small quantity.

According to Brodie, ozone may be obtained from carbon dioxide by passing this gas rapidly through an induction tube and subjecting it to electric action. By this means he succeeded in converting seventy-five per cent., and even eighty-five per cent., of the eliminated oxygen into ozone.

Chemical .- Ozone is a colorless gas with an intense characteristic odor, reminding one in a small degree of chlorine and nitrous acid. Air containing 1 to 50,000 parts of ozone possesses still this peculiar odor (33). According to Soret the density of ozone is 1.658 (34). The active oxygen generated by treating barium peroxide with concentrated sulphuric acid has quite a different, nauseating odor, which causes a choking sensation in the throat (35). Hitherto ozone has only been obtainable in a diluted state, although both Chappuis (36) and Olzewski (37) claim to have liquefied it. Chappuis succeeded in accomplishing this at a temperature of  $-105^{\circ}$ , with a pressure of 125 atmospheres. Olzewski achieved its liquefaction in sufficient quantity to determine its boiling point, which he states is -159°. The liquid was dark blue in color and nearly opaque in a layer a sixteenth of an inch thick.

Professor James Dewar, in his experiments with liquid presence of limewater oxygen, obtained by electric stimulation of the liquefied gas ciable quantity (45).

twenty per cent. of ozone, which was of a very dark blue color—as dark as concentrated indigo. The ozone is exceedingly unstable—to such a degree, indeed, that a beam of light caused it to explode on one occasion. The study of ozone in such concentration requires great delicacy of manipulation.

Scoutetten (38) is authority for the statement that ozone is destroyed at a temperature of 250° C. He passed ozone through a tube heated up to this point.

The solubility of ozone in water was a long-disputed point (39), but all doubt thereon has been removed by the labors and investigations of Engler (40), Nasse (40), Houzeau (41), and particularly more lately Carius (42), Schöne (43), and Leeds (44).

E. Schöne found that ozone obtained by means of the silent electric discharge was soluble in water to the extent of 8.81 c. c. to the litre.

This question has received further confirmation by J. C. Dittrich, a German chemist residing in New York, who has long been experimenting with ozone. He has succeeded in forming a stable compound of this gas with water, by the addition of a very small percentage of hypophosphites.

The statement that the action (125) of ozone on water produced peroxide of hydrogen has been negatived by the experiments of Nasse and Engler (126), Carius (127), and Schöne (128).

Hydrogen peroxide (130) is decomposed by ozone, ordinary oxygen being liberated and water formed. Hydrogen peroxide and ozone are essentially different. Hydrogen peroxide exists in liquid form at ordinary temperature and pressure. Ozone is a gas and is only soluble in water to a small extent, whereas hydrogen peroxide is readily soluble in water.

Statements have been made that oxygen passed through a solution of hydrogen peroxide becomes charged with ozone. Experiments lately made in this city, in which every precaution was taken to exclude all possibility of error, established with absolute certainty that ozone was not produced by any such process as referred to above. No ozone could be detected even with the most delicate known tests. The enumeration of all the distinctive properties of  ${\rm O}_3$  and  ${\rm H}_2{\rm O}_2$  do not lie within the scope of this paper. The reagents employed for their determination are given by Baumann and Gawalowski respectively.

Ozone oxidizes both mercury and silver when moisture is present, but if the metals and the ozone are perfectly dry, no oxidation takes place. If the experiment be sufficiently prolonged, the absorption of the gas takes place, even to the complete disappearance of the volume of oxygen employed. Iodide of potassium in solution is immediately decomposed, assuming a well-marked yellow color. On the addition of a solution of starch, the usual iodine reaction takes place and the solution turns an intense blue (45).

Organic coloring matters exposed to the action of ozone are rapidly destroyed. Chlorine, bromine, and iodine combine with ozone when water is present, forming chloric, bromic, and iodic acids. Ozonized atmospheric air in the presence of limewater produces nitrate of lime in appreciable quantity (45). Ozone precipitates peroxide of lead in an alkaline solution of lead or its acctate (45). It rapidly decomposes all the salts of manganous oxide (45), either in the solid state or in solution, forming the peroxide of this metal (45).

A solution of ferrocyanide of potassium is transformed by ozone into the red ferricyanide (45). Uric acid is oxidized by ozone to alloxanic acid and urea; the albuminates and sugar are also destroyed by its action (45).

A great number of metallic sulphides are rapidly transformed by oʻzone into sulphates, particularly the sulphides of iron, lead, copper, and antimony (45).

Baumann (132) observed that ferrous oxide enters into direct combination with ozonized oxygen, without forming active oxygen or liberating it.

Sulphur and selenium undergo no change when submitted to the action of ozone (46).

Phosphorus acted upon by ozone forms phosphorous acid, which is afterward converted into phosphoric acid (47).

Pyrogallic and gallic acid, dry or moist, are at first turned brown and then decomposed into carbonic acid and water (46).

Fluorine appears to exert some action on ozone. It has been shown by Moissan that fluorine decomposes water, forming hydrofluoric acid, and liberating oxygen in the form of ozone. If a few drops of water be placed on the floor of the experimenting tube and fluorine gas be passed in, a dark fog is seen surrounding each drop, which presently clears and resolves itself into the characteristic blue vapor, apparently more than an inch in thickness, and which is found to be that most interesting condensed form of oxygen—ozone—in a state of great density (48).

Nitroglycerin, gun-cotton, iodide of nitrogen, and boride of nitrogen explode in ozone (47).

Of paramount importance in the economy of Nature is the action of ozone in its relation to ammonia. It forms, as shown by Carius, nitrous and nitric acids, and when water is present, a small quantity of hydrogen peroxide. This reaction is essentially important, as the atmosphere is thereby cleared of its ammoniacal constituents, which are disseminated in the air from the processes of decay and putrefaction (47).

Ozone is rapidly absorbed by a large number of vegetable and animal substances, such as albumin, casein, fibrin, and the blood (50). On passing ozone through blood it turns dark at first and then black; on continuing the process the blood forms a clear fluid, containing no albumin, a quantity of gas being given off during the operation (51).

The bleaching properties of ozone are well known. Lawn bleaching is due to the presence of ozone in the atmosphere. As ozone does not affect the most delicate fibers, it is probable that it will in the near future find employment in industrial bleaching processes. Houzeau states that ozone possesses thirty to forty times the bleaching power of chlorine (52).

The action of ozone as an oxidizer, when in moist condition, is of such an energetic nature that it is difficult to construct apparatus the materials of which are not partly

destroyed by it. Hence cork, India rubber, wood, paper, and most of the metals are not satisfactory substances for use in the construction of such parts of apparatus as may come into immediate contact with this gas (53).

Ozone is believed to act as an oxidizer just as chlorine and peroxide of hydrogen do. Chlorine seizes upon the  $H_2$  of  $H_2O$ , and sets free nascent oxygen; peroxide of hydrogen gives up one atom of unstable oxygen, and again we have nascent oxygen;  $O_3$ , or ozone, gives up one atom of oxygen, and thus again we have nascent oxygen. This at least seems to be a received view, but it appears to me that there is some evidence to show that  $O_3$  oxidizes not by parting with one atom of oxygen but by uniting as  $O_3$ , and thus forming its own special reactions with organic compounds, differing from simple oxidations by nascent oxygen.

Oil of turpentine, however, according to some investigators, absorbs the three atoms of oxygen of which ozone is constituted (47).

Antiseptic Properties.—The antiseptic properties of ozone are well known. Schönbein showed that one three million two hundred and forty thousandth of ozone in the air was sufficient to prevent the odor of decay in a vessel of sixty litres in which had been placed for one minute one hundred and twenty grammes of decaying, stinking meat (54).

Wood and Richardson passed ozonized oxygen through blood in course of decay, with the result that the blood entirely lost its offensive odor, and even regained, to a certain extent, its original odor of fresh blood (55).

Fox (55), who also experimented with ozone, passing it through putrid matter, concluded that the bacteria in this matter were destroyed.

Scoutetten (56) experimented in the same direction. He placed pieces of meat in vessels containing oxygen and also in vessels containing ordinary air, and found that putrefaction manifested itself most actively in the vessels filled with oxygen. He then tried the action of ozone on putrid meat and other decayed matter.

He placed a piece of meat in an advanced state of decomposition, weighing two hundred and seventy grammes, giving out an insupportable odor, in a vessel of five litres capacity, filled with ozonized air; in one minute the meat was completely disinfected.

He repeated the experiment with three hundred grammes of horse manure emitting a strong ammoniacal odor, which odor disappeared immediately.

Stagnant water poured by the investigator into a vessel containing ozonized air and shaken lost its disagreeable odor immediately.

Experiments on a larger scale were conducted in a room of about eleven hundred metres cubical contents. Two heaps of horse manure were placed about ten metres apart in this room. The manure was in an advanced state of putrefaction and emitted a strong ammoniacal odor. It was allowed to remain in the room for forty-eight hours. When the room was fully infected the contents of four vessels, each of six and eight litres, were poured out. The ammoniacal odor diminished perceptibly, but did not en-

tirely disappear, the manure still continuing to emit its disagreeable smell.

The experiment was continued next day, the manure being, however, removed. The same quantity of ozonized air was allowed to flow over the spots where the manure had been lying; the ammoniacal odor disappeared immediately-so quickly, indeed, as to call forth the astonishment of the bystanders.

Fox (57), Geissler, Stein (58), and Chappuis (59) maintained that ozone was not only a deodorizer, but a disinfectant and a germicide.

Experiments have been made with ozone for the preservation of meat, and a patent is in existence covering this

The assumption that ozone, owing to its powerful oxidizing properties, would destroy bacteria, has received the support of many investigators. On the other hand, many have expressed their views on this point in a negative sense. It must be accepted that upon passing ozone through water containing organic matter and living germs the water is completely sterilized and the bacteria are destroyed. Although there has long been uncertainty as to whether ozone had a destructive action on pathogenic bacteria-viz., those producing typhus, cholera, anthrax, etc.this question is at length solved in a manner favorable to ozone. It is now merely a question of method and of quantity of ozone.

According to Schönbein (61), Clement (61), Richardson (61), Boillot (60), and Scoutetten (57), ozone destroys miasmatic emanations. Their experiments establish that the disappearance of infection and putrid effluvia are effected by ozone when it is present in sufficient quantity.

Pasteur says: "It seems, after all, but stating a truism to say that (extremes of temperature, of course, excepted) it is active oxygen which must be regarded as the greatest known enemy to bacterial life, whether from the action of chlorine, nitric acid, ozone, or H2O2. It also follows that these bodies are the best disinfectants." (140.)

In Dujardin-Beaumetz's (62) Dictionary of Therapeutics appears the following:

"Ozonized air is a deodorizer and antiseptic. It arrests or prevents the putrefaction of vegetable or animal matters and removes all bad odors resulting from decomposition of organic substances. Provided that it be highly charged with ozone, the air even becomes a powerful bactericide. But it is with this gas as with other disinfectants -it is a microbicide only in the condition of being so abundant in the atmosphere that the latter would become a deleterious and irrespirable medium. In a quantity that can be tolerated by the respiratory organs, ozone possesses only disinfectant properties and no longer germicide ones."

The vexata questio has lately approached much nearer a demonstration by the labors of Dr. Ohlmüller (63), referred to above.

Dr. Boutens (64), of St. Raphael, in a communication presented at a meeting of the Société pour l'avancement des Sciences, Marseilles, September 23, 1891, states that ozone is a powerful germicide in tuberculosis.

and anthrax bacilli cultures to the action of ozone at blood heat, passed through a special disinfecting apparatus. The cultures were placed on small porcelain saucers. syphilis cultures were destroyed in thirty seconds. The anthrax bacilli, however, withstood the action of the ozone for half an hour. The same results were obtained even when the cultures were inclosed in thin tissue paper.

Oberdörfer's (65) experiments showed that the action of ozone was prevention of the development of bacteria and even their destruction, so that not only prodigiosus and cholera cultures, but even the spores of anthrax were killed.

Dr. Wyssokowitsch (66), of Charkow, convinced himself by a series of experiments that ozone really had a considerable influence on the growth of bacteria; even small quantities of ozone (0.5 to 1.5 mg. in one hundred cubic feet of air) cause a notable difference in their develop-

M. Herman, after a series of experiments on the bactericidal value of ozone, is of opinion that ozone is a powerful oxidizer, and as such a potent microbicide in certain conditions, but that it is never present in the atmosphere in quantity sufficient to play the rôle of an antiseptic. He also states that the favorable therapeutic results obtained in certain infectious maladies, particularly tuberculosis, by inhalations of ozone can not be explained by the antiseptic action of this gas; in fact, ozonized air in quantity sufficient to be a bactericide would be irrespirable (134).

Many observers have turned their attention to the disinfecting rôle that ozone plays in the economy of Nature, and have maintained that it is due to ozone alone that the multiplication of germs of epidemic diseases is prevented. They claim that the spread of epidemic diseases is caused by the absence of or a diminution of the normal quantity of ozone in the atmosphere, and is coincident with the appearance of cholera, etc. Others, however, explain that the absence of ozone is due to the increased number of germs which absorb the ozone, arguing that their opponents mistake the cause for the effect.

One of the latest investigators in this particular direction, M. D. A. van Bastelaer (61), membre titulaire, Académie royale de Belgique, established a series of observing stations throughout Belgium for collecting ozonometric He says that some observers contend that the germicidal action of ozone in the atmosphere would require a proportion of ozone superior to that ordinarily present in the air. That is undeniable, if it were a matter of killing the germs immediately; but the fact must not be lost sight of that the oxidizing action of atmospheric ozone is energetic though slow, and that with time it destroys all organic matters in the atmosphere.

Moffat (67), during the cholera epidemics of 1854 and 1866 in England, made many ozonometric observations which apparently confirmed the coincidence of a diminution or absence of ozone in the air and the appearance of the epidemic.

Cook (68) made similar observations at a series of stations at Bombay in 1866.

Smallwood (69) also noted the fact of a decrease in the Dr. Emil Schnee, of Carlsbad, subjected syphilis bacilli | quantity of atmospheric ozone during an outbreak of cholera in Canada, and Bockel (70) believed that similar conditions existed during the cholera epidemic in Strassburg in 1854. Many other observers in different parts of Europe noted a similar coincidence.

One of the latest reports is from Dr. Onimus (71), who publishes tables of his personal observations made at the Military Hospital in 1883. These tables show an absolute and direct relation between the ozonometric conditions and the intensity of the epidemic.

Physiology of Ozone.—The physiology of ozone appears to be as yet incomplete. Its action may be explained and summed up in the fact that the oxygen in the blood exists in the condition of ozone, and this property is so characteristic that Schönbein and His (72) proposed giving to the red corpuscles of the blood the name of ozonophores (ozone carriers). It has been held that the ozone carried by the red corpuscles of the blood alone prevents its coagulation in the veins. The proof of this theory seems to be established by the fact that by passing ozone through coagulated blood it returns to the fluid state.

According to Dr. Otto Ringk (73), the coloring matter of the red corpuscles (hæmatin) contains seven per cent. of iron. This iron takes up the ozone with avidity (iron having the property of absorbing ozone without decomposing it) and yields it up, as required, to destroy all deleterious matter which may have found its way into the circulation or tissues.

Dr. J. Aulde (142) has stated that protoplasm has the property of absorbing and storing up oxygen, which it receives from the hæmoglobin of the blood, the lymph being the intermediary of transfer. The oxygen thus absorbed is afterward utilized as mechanical energy. It is possible that the protoplasm may, as occasion demands, yield the oxygen again to the intercellular fluid. It also dissociates the oxygen molecule, forming ozone in the organism, where its powerful oxidizing properties are called into play, enabling the protoplasmic cells to eliminate the waste products and continue their reconstructive processes.

M. Girard (75) read a paper before the Academy of Medicine, Paris, at its sitting August 11, 1891, relating to the action of ozone on the blood. He states:

- 1. Ozone transforms albumin into fibrin and the hæmoglobin into oxyhæmoglobin.
- Its prolonged action in the nascent state on this fibrin is to redissolve it and render it incoagulable by acids or metallic salts.
- 3. Ozone is the agent in the transformation of the blood into fibrin, and the effects of the ozonization are produced by the iron contained in the globules, and which under the influence of primary ozonization acquires the property of ozonizing ordinary oxygen.

M. D'Arsonval (76) is of opinion that ozone administered by inhalation diminishes the respiratory capacity of the blood.

Professor Wolfberg (77), Strassburg, proved that ozone had a remarkable influence on the elimination of carbonic acid from the blood.

W. Jaworski (135) proved by experiment on the behavior of carbonic acid, oxygen, and ozone in the human

stomach that of these three ozone increased most the quantity of gastric juice secreted.

Dr. Ringk (79) deduces from his experiments that the internal administration of ozone ozonizes by means of its oxidizing properties the contents of the stomach, which then, in a condition antagonistic to the development of bacteria, pass on to the intestines, where, on the one hand, the action of the ozone allays any inflammation of the muccus membrane that may exist, and on the other hand establishes conditions unfavorable to the growth of bactilli.

He also was of opinion that it manifested its effect in a twofold manner: First, by being yielded up to the contents of the stomach prior to their passage into the intestinal tract for further digestion, consequently converting the contents of the stomach into ozone carriers, and, further, by diffusion, finding its way into the blood.

Binz (80) showed that ozonized air acted qualitatively the same as nitrous oxide, but differently in different individuals. His experiments were made on the living human organism. Sleep was produced by inhalations of ozone, which, however, did not continue longer than twelve seconds after the discontinuance of the administration of the gas. In some cases there was vomiting, in others only an inclination to vomit.

Dr. Ireland (143) states that the action of ozonized air on animals is as follows: 1. It accelerates the respiration and, it may be inferred, the circulation. 2. It excites the nervous system. 3. It promotes the coagulability of the blood, probably by increasing its fibrin. In the blood, ozone loses its peculiar properties, possibly entering into combination with some constituents of the circulating fluid. 4. Animals may be subjected to the influence of a considerable proportion of ozone in the air for hours without permanent injury, but in the end ozone produces effects which may continue after its withdrawal and destroy life.

MM. Labbé and Oudin (81), in a communication to the Académie des sciences, Paris, reporting their experiments in the treatment of consumptives with inhalations of ozone (ozonized air), observed, in subjects whose blood contained oxyhæmoglobin below the normal quantity, that the amount of oxyhæmoglobin was augmented one per cent. at the end of a quarter of an hour's inhalation of the gas. This augmentation persists only twelve to twenty-four hours if the inhalations be discontinued. If they are renewed every day the quantity of oxyhæmoglobin continues gradually increasing, until it attains the physiological figure. Inhalations in subjects with oxyhæmoglobin in normal quantity in the blood only show a slight increase.

MM. Gautier and Larat are of opinion that the production of ozone from the air by means of the electric spark is accompanied by the formation of nitrogen compounds. They doubt that ozone causes an augmentation of the oxyhæmoglobin of the blood and quote M. D'Arsonval as authority that the coloration of the corpuscles of the blood is due to nitrogen compounds. Their clinical experiments with ozone in tuberculous and anæmic subjects were negative.

In the discussion which followed this communication

MM. Labbé and Oudin stated that their opinion as to the therapeutic value of ozone by inhalations of this gas was deduced from their own observations at the following hos pitals: La Charité, Aux Enfans, La Maternité, and Des Enfans tuberculeux d'Ormesson, and from foreign sources.

M. D'Arsonval said that if the ozone produced by MM. Labbé and Oudin did not contain nitrogen compounds, then it was possible that feeble doses of ozone might have therapeutical value (135).

Dr. Gautier (82), in a communication to the Société pour l'avancement des sciences, Marseilles, September 21, 1891, insists on the static bath and effluvia of ozone in the treatment of chronic diseases. In his former publications he lays stress upon the advantages of the static bath, which by its expansive force augments nutrition and hastens all the functions, and which in combination with the effluvia of ozone is able to transform the temperament of a tuberculous subject. He says: "Our aim is the modification of the organs, because the behavior of bacilli, nosologically considered, is as a product and not as a cause."

Dr. Boutens (64) (meeting of the Société pour l'avancement des sciences, September 23, 1891) claims that ozone augments the quantity of oxyhæmoglobin in the blood.

Schultz (83) experimented on animals with ozone in poisonous quantity. His conclusions, drawn from the appearances of the internal organs after the death of the animals, are, that as the mucous membrane of the larynx and trachea did not show the slightest trace of any corrosive action of the ozone, the inflamed and changed condition observed of the lungs arose from impairment of the breathing caused by the recurrent cerebral irritation, which was induced by the ozone taken up by the blood and carried into circulation.

Mulvany (84) observed that ozone had a decidedly invigorating effect on the organs of procreation. There is evidence to show that its action has been to restore virility.

Binz (85) found that even in a high degree of ozone narcosis the heart and blood vessels were not perceptibly affected. This investigator also observed that ozone passed without decomposition through a solution of albumin contained in a vessel 1.85 centimetres deep. This experiment establishes the fact that ozone can not only exist in the fluids of the tissues, the greater part of which contain albumin, but is free to act in the extreme parts of the body.

Dr. C. H. Brown (86) also experimented with the action of ozone on albumin. He found that a solution of this substance was not coagulated by ozone, even when heated to the boiling point. Peroxide of hydrogen, on the contrary, coagulated albumin with considerable evolution of gas.

Engler (131) says that many competent authorities do not agree as to the physiological action of ozone, its importance in its relation to the whole process of respiration, the constitution of the blood, and the general welfare of mankind. Without committing himself to any opinion, he thinks it quite possible that atmospheric ozone may find its way into the lungs. If it be considered with what ease, for instance, chlorine, a gas likewise, and which acts with

such energy on animal substances, finds its way into the lungs, and if it be remembered how difficult it is, by means of the most effectual methods of absorption, to eliminate the last trace of a gas from a gaseous mixture, it must be admitted that the air we breathe may reach the lungs in an ozonized state. The fact, observed by all who have experimented with ozone, that its odor will cling to the hands and clothing without decomposition for some length of time, is a strong argument in favor of the assumption that ozone does find its way into the lungs and blood.

Nutrition.—Dr. P. le Stunf (87) asserts that ozone acts on the blood and the nutrition.

Dr. H. S. Norris (88), in his experiments at the City Hospital, New York, found that the patients under ozone treatment improved in weight, showing better assimilation and consequently increased nutrition.

Dr. Arthur Ransome (89), in his experiments with ozone inhalations, found that the patients gained in weight, showing improvement in the function of assimilation and consequent better nutrition.

Enrico di Renzi (90), Naples, observed that inhalations of ozone were followed by increase of nutrition.

Machines for the Generation of Ozone.—The various processes by which ozone can be produced has engaged the attention of many inventive minds, with the view of constructing apparatus by which this gas could be generated in such quantity as to render it available not only for industrial purposes but also for medical use.

The aim of the apparatus invented has covered a large field, and includes machines intended for the disinfection of hospitals, rooms, and buildings; the preservation of meat, etc.; improving the quality of wines and spirits and aging them; bleaching, etc.

Some of the apparatus devised include contrivances for the production of ozone by means of the slow oxidation of phosphorus. Among the names of inventors of such machines may be mentioned Schönbein (91), A. W. Sangster (92), R. S. David (93), Radulowitsch (94), Lake (95), F. W. Bartlett (96), and Leeds (97). These contrivances do not give ozone, but rather acids exhibiting the usual iodide of potassium reactions.

Others, P. Rumine (98), Turner and Vanderpool (99), and Oskar Loew (100) again have designed apparatus for the production of ozone, utilizing the application of a current of cold air passed over a Bunsen burner or a modification thereof.

There are not wanting machines making use of static electricity for the generation of ozone. Among the inventors of this class of machine may be mentioned H. D. Hall, patent July 31, 1883.

Other inventors have attempted the production of ozone apparatus in which the gas is generated by chemicals.

The great defect in these inventions was the limited quantity of ozone yielded and the consequent expense of working them.

Carius (129) describes an apparatus for the production of ozone by the electrolysis of water with twelve to sixteen Bunsen elements. But this method yields only a small quantity of ozone, and can be recommended for use only when it is desirable to obtain ozone in concentrated condition without regard to its purity.

Apparatus by which ozone is generated by the silent discharge or electric effluvium seemed to offer the best solution of the production of ozonized oxygen or air on a large scale.

The production of a suitable effluvium has led to the construction of many arrangements, all embodying a similar principle, which consists of allowing a stream of oxygen or air to pass between dielectrics (thin plates of glass or other material of different specific inductive powers) interposed between two conductors of a certain length placed parallel. The electricity of high tension is discharged in an effluvium through the glass plates and the oxygen or air passing between them, which is then ozonized.

The pioneer attempt to produce ozone by electricity was the apparatus devised by Schönbein (101), and afterward used by Marignac, De la Rive, Fremy and Becquerel, Andrews, and others. It consisted of a tube arranged somewhat after the manner of a eudiometer, filled with air or, better still, oxygen, placed over mercury or sulphuric acid. Two platinum wires, melted into the tube, were placed in communication with the poles of an induction coil. The electric spark passing between them effected the ozonization of the oxygen. By this method only a proportionately small amount of ozone is obtainable.

The first apparatus utilizing the generation of ozone by the electric effluvium was that of von Babo (102), modi-

fied by Houzeau. This apparatus consists of a glass tube of from one to two millimetres in thickness and forty centimetres long. A platinum wire of somewhat large diameter is placed along the axis of the tube, and a second platinum wire of small diameter is wound spirally round the outside of the same tube. The two wires are placed in communication with the two poles of a Ruhmkorff coil. In order to obtain ozonized oxygen a slow current of this gas is passed into the tube.

Werner Siemens (103) also devised an apparatus consisting of two concentric glass tubes melted together near the top and provided with two smaller tubes, one at each end, for the passage of the gas through the annular space formed by the concentric tubes. The internal tube is covered

with tin foil on the inner side, the external tube being similarly treated on the outside. The whole is placed in a vessel of water, water also being contained in the inner tube, one electrode dipping into each respectively. It will be apparent that in this apparatus the effluvium must traverse the two surfaces of glass and the volume of gas pass-

Ero 1

parallel plates of glass separated by a very small interval, each plate having a sheet of tin at its upper part. These were joined up in pairs with two metallic buttons connected with the poles of a bobbin. A large number of these plates, superimposed and inclosed in a box furnished with tubulures, will produce the effluvium over a very wide surface.

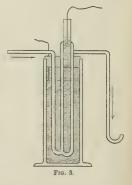

Siemens's arrangement seems to have suggested the arrangement of D'Arnoult, Thenard, and Bertholot.

Of these, Thenard's (105) tube is made up of three concentric tubes, properly joined so as to present three spaces, one cylindrical and the other two annular, separated by glass partitions. The central tube contains conducting liquid, serving as an armature. The outer annular space is filled with the same liquid, which consists of chloride of antimony dissolved in hydrochloric or concentrated sulphuric acid. Two platinum wires, in connection with the poles of an induction coil, serve to convey the electric current to the conducting liquids. The oxygen or air to be ozonized passes through the intermediate annular space. The apparatus in use is placed horizontally.

The Bertholot (106) apparatus consists of a thin glass tube thirty millimetres in diameter and from thirty to thirty-five centimetres in length, closed at the lower end. It is provided with two eduction tubes, one at each extremity. Another thin glass tube, also with closed lower end, is placed in the axis of the larger tube, a little above the upper eduction tube, and fixed to it, the connection of the two tubes being ground with emery to insure perfect

junction. The inner tube is filled with a conducting liquid into which one of the electrodes is introduced. The whole arrangement is put into a glass vessel also containing a conducting liquid, the other electrode dipping into it. The apparatus must be well centered, so that the two surfaces may be equidistant. The oxygen or air passes by way of the eduction tubes through the annular space formed by the two concentric tubes.

Tisley, of London (107), constructed an ozone genera-Ruhmkorff (104) constructed an apparatus formed of I tor, devised by Wills, a modification of Siemens's, and which permits of refrigerating the oxygen passing under the influence of the electric discharge. This was effected by means of a current of cold water. It was claimed that this arrangement prevented the partial decomposition of the ozone caused by the heating of the tube by the electric current.

Brin Brothers (108), of London and Paris, are the inventors of an apparatus generating ozoné. They employ the Bertholot tubes arranged in series.

Among other inventors of ozone machines and apparatus may be mentioned Boillot (109), Wislicenus (110), Kolbe

(111), Yost (112), Fahrig (113), Schereller and Weise (114), and Andreoli.

The rapid strides of electric science and the facility with which currents of high tension are now obtained have also resulted in the development of more perfect apparatus for the production of ozone, and the Ozone Company of this city have established a plant for its manufacture on a commercial scale.

They are the makers of an improved ozone machine which is specially adapted to the needs of the medical profession and may be used for

Fig. 4.—Ozone tube for water elec-

The Ozone Company's machine consists of motor, blower for forcing the air to be ozonized through the apparatus, transformer, and the ozone generator proper. The motor, which may be driven by the current available from any electric plant, supplies also a derived current to the generator by means of a commutator of special construction. High potential is secured by passing the current through a specially wound transformer before it reaches the generator. The motor operates a small blower, which forces the air through an ingeniously devised drying tube and thence to the ozone generating tubes. The generator is formed of a group of ozone tubes arranged in a circle. A modification of the Siemens's tube is employed. The amount of ozone given off by this machine is very great, and will in a very short time make itself apparent, by its characteristic odor, in the most distant parts of a large room or hall. The whole machine occupies only a small space.

Further Comments upon the Value of Ozone in Therapeutics.—The therapeutic value of ozone has been a subject of dispute ever since its discovery by Schönbein, and much has been written pro and con by advocates and opponents.

Prominent among diseases which it has been considered would be benefited by ozone is tuberculosis.

During the past two or three years many practitioners have been experimenting with ozone in the treatment of this disease. Judging from the data now at hand, the results have been satisfactory and worthy of continued effort.

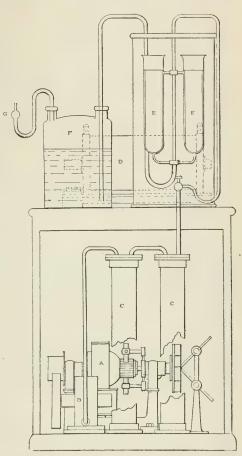

Fig. 5 — Ozone machine. A, motor: B, blower: C C, drying tubes: D, transformer; E E, ozone generators; F, wash bottle; G, goose-neck inhaling tube.

The labors of MM. Labbé and Oudin (116), have already been referred to. They establish the fact that the administration of chemically pure ozone (ozonized air) inhalations has curative value. Their statements are verified by the report of Dr. Boutens (115), of St. Raphael, who, as a result of his experiments, concludes that ozonized air (one tenth of a milligramme to the litre of air) is, when inhaled, absolutely innocuous, that it possesses a constant curative action in tuberculosis, and augments the quantity of the oxyhæmoglobin in the blood.

Dr. Augustus Caillé, of this city, has experimented with the small ozone generators of Labbé and Oudin (136). He reports that in three typical cases of limited apex tuberculosis a local improvement was not obtained; \* that in pertussis the inhalations have a very distinct curative effect, while in chlorosis and anemia inhalations are exceedingly valuable and give better and prompter results than any other form of medication; and, finally, that daily inhalations increase the quantity of oxyhemoglobin in the blood from one to four per cent. in a short time.

Dr. Caillé's observed fourteen reported cases are worthy of careful study.

Dr. Arthur Ransome (117), of Liverpool, treated consumptive patients with inhalations of ozone. He published the results of his treatment, which may be summed up as follows:

Thirteen cases treated—two in the third stage; most of them under observation for more than a year; two of them for two years; only two have distinctly deteriorated in the time, and one of them has died of pharyngeal phthisis.

He found during treatment that there was continued freedom from fever, absence of night sweats, diminution in the amount of expectoration, improvement of appetite and in sleeping power, and much consequent gain in weight,

He also states that if his repeated microscopic examinations were to be trusted, the ozone diminished the number of bacilli in the expectoration.

According to Dr. P. Le Stunf (119), ozone generated by electricity, and in the proportion of one tenth of a milligramme to the litre of air, is quite innocuous, not only to animals, but to human beings in health and disease. By inhalation it increases the oxyhæmoglobin from one to two per cent. Its action is well borne by tuberculous subjects when administered in therapeutic doses. After fifteen to twenty sittings improvement is perceptible. It is a question with him as to whether it does not act as a microbicide in consumptive individuals. It acts on the blood and nutrition. The appetite returns, the digestion improves, the night sweats diminish; sleeping power sometimes reappears, even in patients that have long been tormented by insomnia. There was also an amendment of pulmonary lesions, real retrogression of the local phenomena.

Dr. Otto Ringk's (120) experience is that ozone (ozone water) treatment in tuberculosis gave excellent results.

Dr. Henry S. Norris, of this city, treated thirteen cases of phthisis with ozone water. Of this number, five who had extensive disease were not improved; in seven marked improvement took place: increase in weight, diminution and cessation of cough and expectoration, termination of night sweats.

Dr. C. E. Quimby, Dr. W. B. Wood, Dr. Conkling, as well as several other gentlemen of this city, have also, I am informed, been investigating the therapeutic properties of ozone, and will, no doubt, soon report their experiences.

Aquozon and kodozonol (ozonized cod-liver oil) have been used at the French Hospital, New York. It is stated that the patient showed a steady gain in weight, owing to increased assimilation.

Diabetes.—Dr. Emil Schnee, of Carlsbad, is of the opinion that ozone is the remedy par excellence for diabetes. He states that diabetes is based on the incapacity of the protoplasm for the production of carbonic acid. The use of ozone places the physician in a position to supply this lack of carbonic acid. He has prescribed aquozon to his patients both in this country and in Europe with happy results.

Dr. C. H. Avery, Secretary of the New York County Medical Society, used aquozon on himself in the treatment of this disease. He reports as follows: "I am carefully watching the action of the ozone water in my own case. I first discovered sugar in May, 1885, and have resorted to many remedies. Sugar has been constant but in varying quantity, although starchy foods have been strictly avoided. My observations thus far as to the effect of the water are:

"1. A decided diminution of thirst, so that I used no more than a pint of water for twenty-four hours.

"2. An increase of vital force and muscular strength; a general impression of feeling better.

"3. It procures sound and refreshing sleep and allays nervous irritability. This is specially noticeable.

"During the past week there seems to be a slightly less amount of sugar, amounting to about 3° specific gravity. It is not to be expected that in a case of so long standing sugar will disappear so soon."

Private reports to me from physicians who have experimented with aquozon in diabetes show that marked improvement has taken place.

Cholera.—As cited above, many observers have insisted that there is a direct relation between the appearance of an epidemic of cholera and a diminution of the amount of ozone in the atmosphere. In 1883 Dr. Onimus (121), during the cholera epidemic, made some experiments at Marseilles, in order to personally satisfy himself as to the correctness of the assertions of previous investigators, and also to establish if possible the therapeutic value of ozone in the treatment of this infection. These experiments were conducted at the instigation of M. Gauckler, manager of La Compagnie des chemins de fer de l'État. This gentleman, while on the central committee of meteorology in Alsace in 1865, was much struck by the coincidences in the infected localities. He placed at the disposal of Dr. Onimus the material and staff of La Compagnie P. L. M., in order to carry out the necessary investigations. An ozone plant was installed at the cholera hospital, and the gas was allowed to diffuse itself slowly in one ward, while another, for comparison, was kept free of ozone. Dr. Onimus found that in the male ward no deaths took place during the two days that it was kept under the influence of the ozone. He then experimented in the female ward, with the result that during five days only two deaths occurred, and one of these was a woman who gave birth to a dead child. In his pamphlet on the subject he says: "We can certify that this method, I hesitate to say medication, gives excellent results." \*

<sup>\*</sup> Dr. Caillé stated, in the discussion following the reading of this paper, that in one instance—the inhalations having been kept up for a year—he could now say that there had also been an improvement in the physical signs at the apex.

<sup>\*</sup> During the interval between the reading of the foregoing paper and its publication my attention has been called to an article by Pro-

fessor W. G. Thompson, entitled Notes on the Physiological Action of Ozone Preparations, published in the Medical Record of March 3, 1894.

Professor Thompson gives therein the results of experiments with hydrogen peroxide injected in large quantities into the veins of the animals experimented upon, and deduces therefrom that ozone has a harmful action on the blood. It is obviously an untenable position to attribute the action of hydrogen peroxide to ozone, for it is a wellknown fact in chemistry that these two bodies differ entirely in their composition and behavior toward organic substances. I may instance the marked different actions of ozone and H2O2 on albumin. Moreover, ozone can not exist where hydrogen peroxide is in excess, and, although a dilute solution of hydrogen peroxide may exist where ozone is present in large quantity, yet the latter has a destructive action on the hydrogen peroxide, which it converts into passive oxygen and water (H2O2+O3=  $H_2O + 2O_2$ ). Ozone can be produced only in minute quantity except by very elaborate apparatus, such as used by Dr. Dewar in his experiments with liquefied air, in which ozone was produced in a liquid state, only to resume the condition of passive oxygen with explosive force. Ozone in dilution is not explosive, but reverts gradually to passive oxygen without violent chemical action.

The action of ozone is that of the whole molecule  $O_3$ , whereas the action of hydrogen peroxide is due to the yielding up of its atom of active oxygen.

That ozone does exist in the blood has been proved by actual experiment. The introduction of  $H_2O_2$  into the circulation results in gas embolism and chemical changes in the blood.

The inhalation of hydrogen peroxide in the gaseous state (antozone) is very irritating and causes a feeling of strangulation. Ozone free from nitrous products, as employed by the writer, is, on the contrary, not disagreeable when inspired in moderate quantity, and does not produce any such distress. The irritant effects often ascribed to ozone are mostly due to the nitrous and nitric acids which are present when it is generated by electrolysis of the air.

With regard to the physiological action of ozone, I think that the views now accepted by competent authorities on this subject, and which are referred to in the foregoing article, are sufficiently convincing of the fact that ozone, free from nitrous products and in therapeutic dose, has no injurious effect on the animal organism. The fact that there are many drugs that are violent poisons, and which are injurious and even deadly in their effects if administered in large quantities, does not in any way detract from their value in the treatment of disease. The same line of reasoning will apply to ozone—we deal with it in therapeutic quantity and not in noxious dosage.

Some of the views advanced by Professor Thompson are apparently self-contradictory, and his experiments mainly demonstrate:

- 1. That dogs may be killed by injecting large quantities of hydrogen into their blood-vessels. (Experiments 1 to 6.)
  - 2. That an animal dies when both vagi are cut. (Experiment 7.)
- 3. That hydrogen peroxide destroys animal tissue. (Experiments 8 to 15.)
- 4. That either a certain sample of ozone water was inert or, as no examination was made afterward of the dog's blood, the experiment was inconclusive. (Experiment 16.)

The foregoing facts, with the exception of the last, are well known. Experiments are now in progress upon the same lines as those conducted by Professor Thompson, with preparations that undoubtedly do contain ozone, in order to establish with more certainty the facts observed by so many investigators. Until this is done it can not be maintained that ozone preparations are destructive in their action on the blood, as has been demonstrated to be the case with H<sub>2</sub>O<sub>2</sub>.

## A CASE OF QUININE AMAUROSIS, WITH REMARKS.\*

By JOHN HERBERT CLAIBORNE, M. D.,
ADJUNCT PROFESSOR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC.

On the 16th of December, 1891, I saw Mr. W. A. C. for the first time. He said he was totally blind and had been so for a week. The case was first seen by my father, Dr. J. H. Claiborne, Sr., of Petersburg, Va., who sent me the following note:

"I was called to see Mr. C. on the 8th of December at 8 A. M. Found him in bed, semi-comatose, aroused with difficulty; would only say 'Give me water,' and relapse into same condition. Pulse 100°, full and slow. Respiration slow. Skin moist and warm. Pupils dilated to utmost and not at all responsive to light. No resistance or evidence of sensibility on pulling lids apart. No history of case obtainable except that he retired the night before in usual health. Prescribed a placebo. During the day got a specimen of urine. Found some albumin and one cast. Nothing to justify the gravity of the symptoms. On December 9th he could be aroused more easily. Evidently the deafness was growing better, but no intelligent reply to inquiries and no improvement in the eyes. Became restless and unruly during the day and had to be put under restraint. Gave a few doses of morphine, bromide of potassium, and cannabis indica. Soon became more quiet. Slept the night through and awakened in the morning with hearing and intelligence restored but totally blind. Suspected some effusion at the base of the brain and put him on corrosive sublimate and tincture of cinchona. Advised him to see a specialist."

I therefore saw Mr. C. eight days after he was taken ill. For about two months and a half he had felt badly in New York. He then went to Richmond, Va., where he remained a week. During his stay he took on an average fifteen or twenty grains of quinine a day. This relieved him temporarily, but after he removed to Petersburg his trouble returned and he worked hard for several days opening his stock in a damp shop. He had been sleeping badly the entire time, and finally made up his mind to rest well one night. With this in view he poured the palm of his hand nearly full of two-grain pills of quinine and took them at once before leaving the store. He went home and got to bed early; after that he remembered nothing till he awoke several days afterward perfectly blind.

When I saw Mr. C. for the first time I found him with absolutely no light perception in either eye, either for daylight or for the strong focus of a biconvex lens. He complained, however, of seeing many-colored figures that would change their bue. The seusation of red prevailed. The pupils were fixed and moderately dilated, somewhat irregularly, indeed, the larger axis of the pupils being horizontal. The optic discs of the two eyes were pearl-white and the vessels much smaller than in health, although not so small as they subsequently became. The eyes occupied the position of divergence, and the patient had the typical stare of amaurosis. The sclera seemed preternaturally white, so that the patient presented a very uncanny appearance. I diagnosticated quinine amaurosis imme-

<sup>\*</sup> Read before the New York County Medical Association, April 16, 1894.

diately and put him upon potassium iodide in saturated solution. I explained the nature of the case to him and gave a guarded prognosis. He insisted on keeping up some form of treatment although I told him that nothing would assist Nature in restoring vision.

I increased the dose up to fifty grains three times a day until December 21st, when he exhibited a genuine case of double iritis plastica, slight in intensity however. The pupils were now somewhat irregular and contracted. The iritis slowly improved; by December 31st the inflammation of the iris was entirely gone and the pupils were then moderately widely dilated by the atropine that had been used. On this date the patient said he could recognize the plates and cups at breakfast by a circle of light.

On December 28th I placed him again upon the bichloride of mercury and tincture of cinchona. He laid stress upon the fact that he could see things only by reflected light. Any intense light seemed to blind him completely. He could see a chair in my office when the light was diminished, but could not make it out when the full daylight was allowed to enter. He saw even better by reflected gaslight than by reflected daylight. He could pick up a piece of paper more readily by gaslight than by daylight. He improved so far as to see dimly objects even in another room, and one day when the sky was overcast he said he had read the signs in the street from the car window in coming to my office. During this entire time, although he possessed this much vision for reflected objects, he could not perceive the light of an Argand burner when focused directly into the pupil.

At the end of three months, without further improvement, he removed to the Massachusetts coast. During his stay there -several months-he contracted "pink eye," from which he recovered without further distress.

I saw Mr. C. twelve months after his first appearance in my office. His vision then consisted in the ability to occasionally see dim objects at a distance. He had no vision that was serviceable to him for employment. The optic nerves were then dead-white, and the blood-vessels in the two discs had become mere threads that could scarcely be traced after leaving the disc-in fact, a typical picture of quinine atrophy in the most advanced degree.

It is worthy of note that under the treatment of bichloride and cinchona he fattened so much that he could hardly get into his clothes. His appetite was enormous at the same time. Vision was about the same.

Dr. Knapp saw the patient in consultation on December 23, 1891, and concurred with me in the diagnosis of quinine amaurosis.

I myself have not seen the patient in twelve months. At his last visit to my office I found his condition the same as formerly. He could see indistinctly striking objects by diffused light, but not when looking directly at them. His peripheric vision seemed to be better than the central, and even that appeared to be fickle.

Dr. Knapp saw the patient on October 12, 1893, and kindly permits me to transcribe his notes.

"In the right eye he saw movements of the hand at six feet. With a candle the field of vision was elliptical. It was limited by five degrees beyond the fixation point upward and toward the nose, and extended as far as twenty degrees downward and toward the temple, producing an elliptical field. The vessels were very small.

a candle at twenty feet. Vessels were almost obliterated; pupils irresponsive.'

The deafness that accompanies quinine amaurosis had evidently disappeared when I saw Mr. C.; he did not complain of any, and certainly heard ordinary conversation with ease. I found both membrana tympani slightly drawn in and a trifle pale. Dr. Knapp found at the first examination that he could hear a watch in each ear at half an inch. There was no tinnitus when I saw him, nor was any observed by Dr. Knapp. There was some improvement in hearing after inflation. It is entirely consistent with the history of such cases that the deafness and tinnitus disappear.

The amount of quinine that may produce amaurosis is distinctly indeterminate, and doubtless, as Atkinson (Journal of the American Medical Association, September 28, 1889) says, depends largely on idiosyncrasy. H. C. Wood (quoted by Atkinson) saw temporary blindness result from a dose of twelve grains. As much as an ounce has been given with the result of temporary blindness and stupor followed by recovery (Taussig, Medical Times, April 23, 1864, quoted by Atkinson). Barlow (quoted by Atkinson) narrates a case of a lady with "severe congestive fever, who took forty grains of sulphate of quinine every two hours for ten doses," making four hundred grains. There was no injurious effect from the quinine, and she made a good recovery from the fever. Dr. Emile T. Sabal, of Jacksonville, Fla., narrated to me a case in which twenty grains of the sulphate administered to a young lady produced temporary total blindness. I myself have known a negro woman with tertian ague to take sixty grains at once by mistake and suffer no inconvenience of sight and hearing. There was not even any tinnitus in this case. It would be natural to suppose that physicians who live in the Southern States of our country would see many cases of quinine amaurosis. There is reason to suppose it is rarely seen there. Dr. Sabal, referred to above, has only seen one case in an experience of thirty years in Florida. My father, Dr. Claiborne, in an experience of forty years in tide-water Virginia, has seen only one case—the one reported herewith. It will be observed that the patient was not a native of the section, but was from New York. It is not improbable that a tolerance for quinine is established by a long sojourn in malarial regions. I believe the opposite also to be probable, that one born and raised in a malarial country may lose his tolerance for quinine by sojourn in a colder region.

In 1881 Dr. Emil Gruening (Archives of Ophthalmology, B, x, p. 81) compiled thirteen cases of quinine amaurosis, the first being that of Giacomini, quoted by Biaz. Since that time the literature has been swelled considerably. Atkinson, in the Journal of the American Medical Association, quoted above, recapitulates the histories of forty-nine cases, and follows with a masterly review of them. Dr. Alice Wakefield, in the New York Polyclinic, August, 1893, recites a case of quinine amaurosis, in which reference is made to Atkinson's compilation. She states that as many as fiftyfive cases have been reported. Pische, in the Medical "In the left eye he had perception of light; could recognize News, July 29, 1893, adds a case. This, together with

Dr. Wakefield's and mine, make fifty-eight. There are probably more.

The symptoms and signs of quinine amaurosis are marked and fairly constant. They are blindness, total or incomplete, which usually comes on suddenly; a dead, pearl-like pallor of the optic nerve, strikingly simulating the pallor of atrophy, accompanied by greatly contracted retinal vessels, both arteries and veins, with occasionally total disappearance of an artery or a vein; concentric or elliptical contraction (Knapp) of the field of vision. The long axis of the field is usually horizontal or slightly downward or outward. Dilatation of the pupils, which are irresponsive to light; partial color blindness in the field of vision. The color sense usually returns entirely. In my case there was distinct divergence of the visual lines. This was also observed by Diez, Browne, and Knapp. Roosa remarked nystagmus in a case of his; Knapp also. Dickinson found congestion of the retinal and chorioidal vessels and a distinct tumefaction of the disc. I found the edges of the optic disc in one eye slightly hazy.

In a communication presented to the College of Physicians and Surgeons, Philadelphia, November, 1890, Dr. G. E. de Schweinitz gave the results of some experiments made on dogs for the purpose of determining the lesion in quinine blindness. This was followed by a paper in 1891 in the American Ophthalmological Society Transactions. Similar work in this direction has been done by H. Bruner, Ueber Chinin-Amaurosis, Zurich, 1882. An extract of this work may be found in Nagel's Jahresbericht. (I am indebted to Dr. de Schweinitz for this reference.) Bruner's work and de Schweinitz's are quite similar, but the latter's is more exhaustive and in reality furnishes all the light we have upon the lesion in quinine amaurosis.

De Schweinitz gave quinine hypodermically to dogs in quantities of from one to four grains to the pound, with the result of producing blindness in from three to fourteen hours. The effect of the drug was obtained more readily by administering the bimuriate of quinine with the carbamide of urea. The symptoms of vomiting, staggering, and convulsions attended the blindness, with two exceptions—in these there were no symptoms attending the blindness.

The ophthalmoscopic picture was similar in every case to that seen in the human subject. The pupils in all cases were immovably dilated. In one case there was thrombosis of the central vein. Examination with the microscope showed that toxic doses of quinine could produce thrombosis of the central vein, and that neither neuritis nor atrophy, in the true sense of the word, was present in the animal longest blind (nearly a month), but that there appeared to be a species of ædema between the optic nerve and chiasm.

De Schweinitz then undertook additional experiments to settle four points:

- Whether blindness could be produced in dogs by other salts than those used.
- 2. Whether the prolongation of quinine amaurosis would produce true atrophy.
- 3. Whether the production of thrombosis or embolism is to be expected in severe cases.

4. Whether the apparent degeneration of the cells of the cuneus found in the first experiments was the result of the hardening process or due to true lesion from the drug.

His subsequent experiments showed that blindness could be produced effectively by other salts of quinine, dissolved with the aid of tartaric acid or dilute hydrochloric acid.

In regard to the second proposition, he proved by microscopic examination that prolonged quinine blindness caused a true atrophy of the optic nerve, chiasm, and tracts.

In regard to the third proposition it was shown that thrombosis of the central vessels may be expected in severe cases.

He found, however, that the degeneration of the cells of the cuneus was due to the hardening process and not to the drug.

Let it be remembered that in the case I herewith report there was no thrombosis of any of the vessels, although the ultimate result shows the case to be the most severe on record.

From the study of this subject the following conclusions may be drawn:

- 1. Quinine in toxic doses may produce blindness.
- 2. The toxic dose is distinctly indeterminate.
- 3. The duration of the amaurosis varies largely.
- 4. The field of vision remains contracted.
- 5. Central vision usually returns to the normal.

There is color blindness at first; the color perception is ultimately restored within the central field.

- 7. The ophthalmoscopic picture is that of white atrophy.
- Experiments on dogs show that there is atrophy of the entire optic tract.
- The same experiments show that the cells of the cuneus are probably not affected.
  - 10. Treatment is of no avail.

# REPORT OF A CASE OF BULLET WOUND, WITH TREPHINING.

BY JOHN FRANCIS BURNS, M. D., VISITING SURGEON TO ST. JOHN'S HOSPITAL, LONG ISLAND CITY.

W. L., aged nineteen years, male, was brought by ambulance to the hospital one evening. Examination revealed a bullet wound of the left temporal region, and Dr. Bumster and myself could find no powder marks of the surrounding region. The young man was very violent and had been drinking. I could find no aperture of exit, and, it being an open question whether the bullet had entered the brain (the temporal muscle in the fossæ at this point being very thick), I exposed the temporal bone by an elliptical incision. This revealed a circular opening evidently made by a bullet of small caliber. I then gently insinuated a Nélaton's porcelain-tipped probe through the opening; it passed by its own weight for about two inches, when something hard was met. I then, with the assistance of Dr. Bumster, trephined with a three-quarter-inch crown trephine, including half the circumference of the aperture. Another probing with the enlarged opening confirmed the original conclusion of "foreign body." I carefully introduced a suitable

forceps and removed a large section of the circle of bone which had been driven from the skull into the brain tissue. The tract ended here and I could find no trace of the bullet. Noticing some clotted blood posteriorly to the channel mentioned, I incised the dura and carefully irrigated the neighborhood of the wound. This brought away four other smaller fragments of bone which completed the circle driven in. I then allowed the probe to follow this channel toward the tentorium cerebelli somewhat obliquely upward and backward and the channel ended.

The large fragment of bone which I removed anteriorly was very much stained from the lead bullet. I gently irrigated the channels, which removed some disintegrated brain substance, established drainage, and dressed the wound antiseptically. The boy rallied well from the ether and made a speedy recovery devoid of complications. He had much delirium for the first few days-a combination of whisky and laceration of brain substance-but manifested no other symptoms which could be attributed to nervous lesions. When questioned as to the manner in which the injury was inflicted, he either denied all knowledge of the occurrence or said, " They did it." The boy finally recovered without any loss of function and seemed the same as he always had been. I informed the coroner of the case and careful official inquiry showed that the wound was self-inflicted, eye-witnesses testifying to the occurrence.

This case presents many more features illustrating points in connection with bullet wounds generally:

- 1. That the bullet should have taken one course and the large fragment another, or did the bullet afterward drop out? Such cases have been mentioned.
- 2. That the fragment of bone should have been so deeply stained with the lead and yet no powder marks present. It is easy to see how wrong deductions might be made by a surgeon from these facts.
- 3. The fact of the absence of powder marks and the wound being in the left temporal region of a right-handed man is often a disputed point. Here we have a living example.
- 4. It also shows what care must be exercised in accepting the ante-mortem statements of such persons. This boy would be considered very rational by nine out of ten persons when he told me "They did it." He might as well have named Tommy, Jimmie, or Dannie.
- 5. The region traversed by the bullet, as near as I am able to locate without dissection, was the seat of the most important centers in the brain, but the bullet must have passed right between them, as the boy has no lesion left to indicate their involvement.

I hope to be able to watch this case in the future, as it certainly will be interesting.

426 Jackson Avenue, April 15, 1894.

The Medico-chirurgical College, of Philadelphia. - Appointments have recently been made as follows: Dr. Isaac Ott, of Easton, Pa., professor of physiology; Dr. William E. Hughes, professor of clinical medicine; Dr. Albert E. Roussel, assistant professor of clinical medicine and of practice of medicine; Dr. Charles W. Burr, clinical professor of nervous diseases; Dr. William C. Hollepeter, clinical professor of diseases of children; Dr. Arthur H. Cleveland, clinical professor of laryngology; Dr. Edward B, Gleason, clinical professor of otology; and Dr. William Blair Stewart, lecturer in therapeutics.

## POTASSIUM PERMANGANATE AND ZINC SULPHATE

## AS INJECTION IN GONORRHŒA.\*

BY JOSEPH D. FARRAR, M. D., BALTIMORE.

INJECTIONS in gonorrhea should be made with great care. The germs of this disease are in a great part lodged in the submucous tissues and beyond the contact of any agent intended for their destruction. Usually, from the tenth to the twentieth day after suppuration is noticed, if the foregoing measures have been faithfully carried out, the character of the discharge is changed from the yellow, thick, and profuse pus of acute gonorrhea to the scant, whitish milky fluid of the later stages of the inflammation, and with this the painful symptoms have also disappeared. The urethral syringe should be selected with great care. It should contain about two drachms, have a conical nozzle, and can be used with one hand. The long-nozzled, pointed syringe should never be employed. In its use the point strikes against the mucous membrane, causing an exaggeration of the inflammatory process here, not infrequently resulting in stricture. An injection should be performed as follows, and each patient should be thoroughly instructed before he is intrusted with its employment upon himself.

The bladder should not be emptied. The bottle containing the injection fluid should be shaken, and a quantity sufficient to fill the syringe emptied into a cup and drawn into the instrument as needed. The syringe is now held with the point, and the piston pushed up until the air which may have entered with the fluid is expelled. A small quantity of oil or vaseline is rubbed upon the tip of the syringe. The patient should sit upon the edge of a hard chair, the buttocks projecting slightly over it, the feet separated and the thighs relaxed. In this way all pressure or tension upon the perineal muscles is removed, and the injected fluid finds its way backward to a sufficient depth, or the patient lies down, the glans penis is held between the fingers of the left hand, and the index finger is carried through the ring on the end of the piston, while the cylinder is grasped between the thumb and middle finger. The conical end of the syringe is now introduced into the meatus, and pressed in with sufficient firmness to prevent the escape of the fluid while the contents of the cylinder are slowly emptied into the urethra. In making an injection the urethra should be well distended, so that all parts of the mucous surface, as well as the follicles, may be brought in contact with the fluid. After holding the injection in the urethra for from three to five minutes it may be allowed to run out and the patient directed to empty his bladder. A second quantity, about a third less than the first, is again injected. These injections should be used night and morning and, if convenient, at noon. In the cases treated in the surgical dispensary of the Baltimore Medical College I used a quarter of a grain of sulphate of zinc and an eighth of a grain of permanganate of potassium to the fluidrachm for injections, with mucilage

<sup>\*</sup> Read before the Baltimore Medical Association, April 9, 1894.

of acacia and distilled water as a menstruum. When these drugs are given together most excellent results follow their use. From June 15, 1893, up to March 20, 1894, one hundred and eleven cases have been treated in the surgical dispensary, and of this number eighty-seven cases by the method mentioned, with a restricted diet, in which a cure was effected in from three to four weeks.

In the cases thus treated no unpleasant complications arose, as after improper use of injections. Some authors advise the use of the internal treatment altogether.

They are contraindicated in the acute inflammatory and suppurative stages of this disease.

Topical remedies are divided into three classes:

1. Those which, when strong enough to exert a sufficient germicidal action, are locally so irritating as to be harmful or unbearable. This class includes nitrate of silver, carbolic acid, chloride of zinc, iodine, chloral, salicylic acid, and creosote, all of which have been faithfully tried in many cases and by competent surgeons, the concurrent testimony being that when used in sufficient strength to sterilize the discharges they produce an amount of irritation and swelling, ardor urinæ, chordee, and even exceptionally urethral ulceration that far outweighs any advantage to be derived from their antiseptic properties.

2. Those which are such feeble antiseptic agents that they can not be depended upon to destroy all the bacteria found in urethral discharges. Among these may be mentioned resorcin, thallin, quinine, acetate of zinc, lanolin, sulphur waters, tannin, alum, hydronaphthol, and cadmium sulphate. The clinical evidence and experimental evidence coincide as to most of these drugs. Each has had its more or less enthusiastic advocates, but when given a wider trial has been found disappointing, while bacteriologists have shown that the germicidal action is either limited to a very few varieties of bacteria or is slow and uncertain.

3. The third class includes a number of agents which, while open to the same objection of too feeble or too limited antiseptic action, have the additional drawback of insolubility in ordinary media and of occasionally becoming mechanically irritating from the formation of concretions. Among these are iodoform, calomel, bismuth subnitrate, oxide of zinc, and other insoluble powders. It must not be supposed that this list is intended to be even approximately complete. It might be increased literally a hundredfold, and nothing could better demonstrate the absurdity of empirical methods than the dozen of ridiculous formulæ and the hundreds of useless drugs which have from time to time been recommended for use in the various forms of urethritis. So far, however, as they are antiseptics, they would be found in one or the other of the above classes. There are certain agents which have been purposely omitted from the classification, but which, as ordinarily employed, might with considerable propriety have been included. These are corrosive sublimate, sulphocarbolate of zinc, boric acid, peroxide of hydrogen, and salicylate of bismuth in various combinations, all of which have practical value in attempting by topical freatment to secure asepsis in an inflamed urethra. They may be used in different proportions and either singly or in combination.

### NEW YORK MEDICAL JOURNAL.

A Weekly Review of Medicine.

Published by D. APPLETON & Co.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 30, 1894.

#### THE LEAVEN OF SCIENCE.

AT the dedication of the Wistar Institute of Anatomy and Biology of the University of Pennsylvania, on May 21st, a report of which is published in the University Medical Magazine for June, Dr. William Osler, of Baltimore, delivered the principal address. It was a fitting tribute to the memory of the men who have from time to time occupied the chair of anatomy in that university. Dr. Osler closed his address with substantially the following remarks: There was great need, he said, in the colleges of this country of men who were thinkers as well as workers-men with ideas, and men whose energies were not sapped in the treadmill of the class-room. In the laboratories of the institute opportunities would be given for this higher sort of university work. The conditions about us were changing rapidly; in the older States utility was no longer regarded as the test of fitness, and the value of the intellectual life had risen enormously in every department. The "leaven of science" gave to men habits of mental accuracy and modes of thought which enlarged the mental vision and strengthened the "sinews of the understanding." Science had done much, and would do still more, to alleviate the unhappy condition in which so many millions of our fellow-creatures lived, and in no way more than in mitigating some of the horrors of disease. What, after all, Dr. Osler asked, was education but a subtle. slowly effected change, due to the action upon us of "the externals," of the written record of the great minds of all ages, of the beautiful and harmonious surroundings of Nature and of art, and of the lives, good or ill, of our fellows? These alone educated us, these alone molded the developing mind. These influences would lead successive generations of youth from matriculation to graduation in the special school: The complex, varied influences of art, of science, and of charity-of art, the highest development of which could come only with a sustaining love for ideals; of science, the cold logic of which kept the mind independent and free from the toils of self-deception and half-knowledge; of charity, in which we of the medical profession, to walk worthily, must live and move and have our being.

#### MINOR PARAGRAPHS.

RHYTHMICAL TRACTIONS ON THE TONGUE AS A MEANS OF RESUSCITATION.

M. LABORDE, of Paris, has given much attention to the procedure of making rhythmical tractions on the tongue as a means of reviving the respiratory function in cases of suspended animation—such as asphyxia neonatorum, asphyxia from submersion or from the inhalation of poisonous gases, and apparent death occurring from the action of anæstheties. As the Gazette medicale de Paris remarks, he has made the method quite his own and has popularized its use. He has published a work on it, with the somewhat startling title of The Physiological Treatment of Death. At a recent meeting of the Société de biologie, a report of which appears in the Union médicale for May 22d, M. Laborde explained the efficacy of the manœuvre as due to nervous action through the medium of the glosso-pharyngeal and the superior lingual nerves, whereby the respiratory center of the bulb, which is very tenacious of its irritability, is roused to action.

#### MORE NEWSPAPER MEDICINE.

THE politician who would not allow such a little thing as the constitution to "stand between friends" was a stickler in comparison with the author of a dispatch from Paterson, N. J., published in the Sun on Friday of last week, concerning a woman who, having been badly frightened by a stroke of lightning, called her daughter's attention to her trembling hands. "As she held them up to look at them herself," the dispatch goes on to say, "one of her eyes fell out into her lap. The other eye fell back into its socket and appeared to be lost in her head." It is added that the doctor in the case "says she has been afflicted with tumor of the nose, and that the fright snapped the muscles of the eyes and the balls became dislodged. The eyeball that fell back into her head is coming back in its place, and to-day it can be partly seen through the small opening of the eyelids." The final fate of the eye that dropped into her lap is not stated.

#### ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 26, 1894:

DISEASES.	Week ending June 19.		Week ending June 26.	
DIOBASES.	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	6	1	12	7
Scarlet fever	114	17	18	14
Cerebro-spinal meningitis	4	4	0	1
Measles		12	90	7
Diphtheria	244	60	254	48
Small-pox	15	3	18	1
Tuberculosis		84	106	116

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 17 to June 28, 1894:

EDIE, GUY L., Captain and Assistant Surgeon, is granted leave of absence for one month, to take effect on or about July 1, 1894.

Gibson, Joseph R., Major and Surgeon. The leave of absence granted on surgeon's certificate of disability is extended three months on surgeon's certificate of disability.

MERIMETHER, FRANK T., First Lieutenant and Assistant Surgeon, is granted leave of absence on surgeon's certificate of disability, with permission to leave the limits of the department.

MERRILL, James C., Major and Surgeon, is relieved from duty in the office of the Surgeon General, to take effect July 1, 1894, and ordered to report in person to the commanding officer, Fort Sherman, Idaho, for duty at that station. He is also granted leave of absence for three months, to take effect July 1, 1894.

#### Society Meetings for the Coming Week:

Tuesday, July 8d: Medical Society of the County of Broome (quarterly), N. Y.; Union, N. J., County Medical Society (quarterly); Chittenden, Vt., County Medical Society.

[N. Y. MED. JOUR.,

THURSDAY, July 5th: Washington, Vt., County Medical Society.

### Proceedings of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting of Tuesday, June 5, 1894.

The President, Dr. EDWARD E. FISHER, in the Chair.

Tabes with Homonymous Hemianopsia. - Dr. Frederick Peterson presented a man, aged fifty, married, a bricklayer, without hereditary stain. He had had a chancre twenty-eight years before. Four years ago he had first noticed that his vision was growing dim, although eighteen years ago he had had a transient diplopia for three weeks. He had been under observation at the Vanderbilt Clinic for a year, during which time there had been little progress in the main features of the case. There were absence of the knee-jerks, the Romberg symptom, sharp shooting pains in the legs, principally the right leg, dull pain in the back, impaired muscular sense, slowness of micturition, Argyll-Robertson pupils, and some optic atrophy. He had never had crises, and there was no trophic disturbance, girdle sensation, or anæsthesia. In April, 1893, he had noticed his hemianopsia for the first time. He thought it came on suddenly, but there was no accompaniment in the way of headache, faintness, loss of consciousness, or other disagreeable symptom. The left visual field was limited to the upper nasal quadrant; the right, to the upper temporal quadrant. Dr. Peterson said that Gowers had described a case of locomotor ataxia with double temporal hemianopsia, but in a carsory examination of the literature on the subject he had been unable to find another reference to a case of this kind.

Dr. WILBUR B. MARPLE said that when he had examined the patient's eyes, in July, 1893, he had found the condition described by Dr. Peterson-namely, the left field limited to the upper nasal quadrant, and the right field to the upper temporal quadrant, excepting for form, which extended over the upper nasal side. Over this area the patient recognized motions of objects, but the recognition of colors, including white, was limited to the temporal quadrant. At a second examination, made on June 1, 1894, the same condition of affairs had been found, but the field of the right eye was somewhat more contracted, so as to be more exactly quadrantic. Dr. Marple said he had recently seen a man who, while coming up from a cellar, had struck the top of his head violently against a projecting beam. He was unconscious for some time, and afterward there was atrophy of the optic nerve, with lateral hemianopsia, color defects, etc. His ocular symptoms had probably been due to atrophy of the nerve, which had taken place in this peculiar manner. This same explanation would perhaps apply in the case shown by Dr. Peterson.

Dr. William M. Leszynsky said he had never seen a case of tabes with symptoms exactly similar to those in Dr. Peterson's patient. The fact that both eyes were affected made it rather difficult to locate the lesion. He was inclined to ascribe the conditions to a peculiar form of atrophy of the optic nerves.

The PRESIDENT said that, as suggested by Dr. Peterson, the peculiar conditions in this case might be due to changes in the

vessel walls, probably a syphilitic endarteritis. He called attention to the fact that the optic atrophy had been progressing very slowly.

Paralysis Agitans with Tremor.—Dr. Peterson presented also a man, aged sixty, a wheelwright. He had first come under observation in May, 1894. He had the characteristic mask-like rigidity of the face, and the attitude of Parkinson's disease was marked, with the stooping shoulders, bent back, and crooked elbows and knees. The hands and fingers had the characteristic position, but there was no tremor anywhere in the extremities or head. His voice had the monotony and something of the festination of the speech of paralysis agitans. There was at times a sort of propulsion in his gait.

Dr. Leszynsky said he had seen two cases similar to the one presented by Dr. Peterson. One of these he had kept under observation for a long time, and in that instance the tremor had developed late in the course of the disease. The speaker referred to the fact that recent investigations had shown that the pathological changes met with in paralysis agitans were identical with those found in senility.

Dr. Edward B. Angell, of Rochester, called attention to the fact that typical cases of this disease were rarely met with.

Bradycardia.—Dr. A. D. ROCKWELL showed a young man who had been under his observation for some months, and during that time his pulse had never been found to be above forty-nine a minute. The patient was in fairly good health, although he suffered from some digestive trouble and was very nervous. A strong galvanic current applied directly to the neck reduced the pulse to forty-three.

The President said that during the past year he had had a patient under his care whose pulse averaged about fifty; occasionally it rose as high as sixty. The man had a constant feeling of dread, and was somewhat neurasthenic.

Dr. Leszynsky said that in one case of bradycardia that had come under his observation the pulse-rate had been 32, and the patient had suddenly gone into collapse. He had seen a number of instances of slow pulse in patients who suffered from the grippe; in these cases the slow pulse had been accompanied by high temperature. During the past winter he had seen a patient whose pulse was 84 and the temperature in the mouth 104:5°; the pulse never went above 90. In a case of exophthalmic goitre recently under his care the galvanic current (four or five milliampères) applied in the region of the cervical sympathetic had reduced the pulse from 120 to 100.

Dr. Angell said that in gouty individuals or in those suffering from lithæmia or neurasthenia there might be a slow pulserate. A number of such instances had come under his observation.

The President said be had seldom been able to moderate the heart-beat by the application of the galvanic current to the neck, either in ordinary cases or in exophthalmic goitre,

Dr. ROCKWELL said that, while his patient presented no evidence of lithæmia, he was certainly neurasthenic. He had never seen any good results follow such mild applications of electricity as those mentioned by Dr. Leszynsky. It was seldom that a patient was able to bear more than thirty-five or forty milliampères applied to the neck; this patient, however, could bear seventy-five milliampères, and it was only when that strength was used that the pulse-rate was at all affected. In exophthalmic goître he had frequently seen the pulse reduced very decidedly by the application of the galvanic current; other cases, again, were not affected by it at all.

Microscopic Sections showing Weigert's New Neuroglia Stain.—These sections had been prepared by Professor C. Weigert and were exhibited by Dr. WILLIAM J. MORTON.

An Improved High-tension Coil was exhibited by Dr. ROCKWELL. The interesting feature of this electrical apparatus, which the speaker said he had presented in a rather crude form about a year before, was the fact that he had in a single coil all the various lengths and thicknesses of wire which were now found so essential in the electrical treatment of certain diseases, especially in gynæcology and neurology. By means of this apparatus the current could be increased from absolute zero to the maximum required.

Dr. LESZYNSKY said the majority of faradaic machines were so made that we could not graduate the current from zero, and on that account it was too strong in certain instances, not only for the purpose of treatment, but also for that of diagnosis.

#### COLLEGE OF PHYSICIANS OF PHILADELPHIA.

SURGICAL SECTION.

Meeting of April 13, 1894.

(Concluded from page 727.)

Demonstration of a New Surgical Engine,—Dr. M. H. Cever exhibited an improved surgical engine, with its various shaped drills, burrs, trephines, and guards, used in cutting bone for surgical operations.

The drills were made with three spiral blades, giving them the appearance somewhat similar to a twist drill. The effectiveness of these blades was enormously increased by a spiral screw, forty-four threads to the inch cut around the blades of the instrument. This device necessarily added forty-four teeth to the inch upon the edge of each cutting blade. The individual teeth were so arranged with reference to one another that the cut made by one tooth was overlapped by that of the one next following. These instruments were used for drilling into bone and opening the medullary canal, as in the case of osteomyelitis, or in removing sequestra which had formed in the long bones. After the bone had been cut down upon and the cloaca found, it was opened up with the spiral drill, and by forcing the instrument laterally the side portion would cut the intervening bone away, thus making a groove down on the dead bone. If the opening thus made was not large enough, burrs of various sizes, made on the same principle as the drills by increasing the number of spiral tooth blades in definite relation to the size of the cutting instrument required, could be used to enlarge the groove to any desired size. These burrs were very useful for removing the dead or abnormal bone, uncovering nerve canals, for operating on the bony structures in relation to the ear, or in the nasal chamber. For the latter work Dr. Cryer exhibited a lighter engine made on the same principle as the large one, except that it was made to be turned by the foot of the operator.

The most important instruments exhibited had been those used for making a section of the brain case. These were of two characters, the circular saw and the spiral osteotome. The circular saw was an inch in diameter and a sixteenth of an inch in thickness, having a guard attached to the end of the hand-piece to regulate the desired depth to be cut. This instrument had been successfully used in an operation for the removal of the Gasserian ganglion. It had cut with great rapidity, but as the brain cases varied in thickness, the operation had to be completed with mallet and chisel. The spiral osteotome had overcome this objection, the cutting portion being made on the principle of the drills already described. It was half an inch in length and an eighth of an inch in diameter. The point of the instrument when in use was guarded by a rounded, button-like attachment connected with the nose of the hand-piece by means of a shank and collar. The free end of the burr was doweled

into a seat in the guard in which it revolved; this steadied the whole instrument when in use, giving added rigidity to the burr shank and holding the burr and guard in permanent relation to each other. The principle involved in the instrument described was simply that of a saw cutting in a line with the axis of the shaft of the burr and not at right angles to it, as in the circular saw. Such an arrangement allowed of cutting in any direction and upon curved lines. This was especially valuable in resection of the brain case, inasmuch as fenestræ of any desired shape or size might be speedily made.

In operating for the removal of a portion of the brain case with this instrument after a division of the soft tissue by the scalpel, an opening five sixteenths of an inch in diameter was made by a trephine mounted in the engine hand-piece; it was passed completely through both tables of the skull and a button of bone removed. There was no danger of injuring the dura with the trephine if it was carefully used. The opening thus made afforded a means of entrance for the osteotome, which, with its protecting guard, was next inserted, and the section made along the line previously determined by running the engine at a high rate of speed and forcing the bit laterally in the direction desired. The button-like guard at the point of the osteotome prevented injury to the dura, which was pressed or directed away by it from its attachment in the line of the cut as the instrument progressed.

Dr. Cryer made several demonstrations on the bones and head of the cadaver, showing the rapidity with which bone could be divided and various operations performed, such as drilling and cutting bone, and uncovering the nerves in the superior and inferior maxillæ. The safety with which the operation in opening the brain case had been done without injury to the dura was very gratifying. He said that at a meeting of the Philadelphia County Medical Society, held February 14, 1894, during the discussion of an operation for the removal of the Gasserian ganglion by Dr. W. W. Keen, in which this engine had, in his opinion, been successfully used, Dr. John B. Roberts had made the following remarks: "With regard to this elaborate instrument, it seems to work very satisfactorily, yet for my own work I should rather use a sharp chisel with my own hand and my own mallet than any mechanical device. These are apt to get out of order and must be at some place where they can be kept in order. What we want to do is to train our own hands to do the work, and not be dependent upon any mechanical device." This statement had indicated to Dr. Cryer an erroneous position with regard to this class of instruments which it seemed to him ought not to go uncorrected.

He was a little fearful that surgery would take a back seat if all its mechanical devices were done away with. He heartily agreed with Dr. Roberts when he said, "What we want is to train our hands to do the work," and he would strongly advocate the highest possible attainment of manual skill as a necessary prerequisite in the performance of all surgical operations; but, continued the speaker, when he adds that we should "not be dependent upon any mechanical device," he was inclined to take issue with him on the ground that his statement was contradictory from the very fact that he himself advocated the use of a mechanical device, albeit a very crude one, in the shape of a mallet and chisel. This machine had now been so simplified and perfected that there was little or no danger of its getting out of order. It was not nearly so complicated as the most simple sewing machine, yet men and women ran this, and who would say, Go back to the ordinary needle and do away with the sewing machine?

Dr. L. W. Steinbach said he had had the pleasure of having Dr.Cryer perform one of those operations for him recently in a case presenting some difficulties from the fact that repeated

operations had been performed on the inferior maxillary portion of the fifth nerve, and he had been delighted with the working of the engine, so far as the bone-cutting had been concerned, but he believed that the amount of blood lost was greater than at the previous operations, where the ordinary chisel and mallet had been employed. As a mechanical device he could praise the instrument, and he did not wonder that Dr. Cryer was enthusiastic, although he could not agree with him that it was a great advantage to a surgeon to learn to use such a complicated machine. It might be of much advantage in a hospital where much work was done.

Dr. ROBERTS said he had been very much interested in trephining with the surgical engine some fifteen years ago, and had written an article on the subject after experiments with a flatheaded burr. He now preferred the chisel and mallet for opening the skull, and used a small sharp chisel shaped like an osteotome.

Dr. J. WILLIAM WHITE said he had never had the advantage of seeing this particular instrument used in actual operations, but he could see no theoretical reason why it should not be employed with great advantage to surgeon and patient. He supposed there was no surgeon who did more trephining than Mr. Horsley, of London. He had noticed last summer that Mr. Horsley had employed a powerful electric engine in which he had used a burr or saw, and could cut out a section of bone with a great saving of time. It looked to the speaker like a dangerous thing, and it had been remarked that there was force enough to drive a part through a man had any portion broken loose. With it, however, Mr. Horsley had greatly reduced the time required for exposing a brain tumor, and did the work with great delicacy and with much less shock (if shock was the result of jarring and concussion of the brain) during an operation than would be inflicted by a mallet and chisel. He, however, had cut from without inward. This was the first time the speaker had seen a machine cutting from within outward. It had been observed here that it actually pushed away the artery from the bone without injury. He could not understand why such an operation should be attended with any more loss of blood than by the usual methods, and he did not know why Dr. Steinbach's operation should have been any more bloody. Of course, this view was purely theoretical; but as he had found a surgeon like Mr. Horsley, who was one of the most expert operators on the skull, using a machine which had seemed to him of distinctly less advantage than that, the action of which had just been demonstrated, he believed this engine had a future, especially for use in the hospitals, either for nerve resection through bone or for work upon the brain.

Dr. M. H. CRYER said he had not much to say, for the demonstration had been the principal part, but he was inclined to answer his friend Dr. Steinbach. He believed from his experience and the experience of others, that in second, third, or fourth operations on the same part there was generally more hæmorrhage, for the simple reason that the small arteries were dilated, and small capillaries had become arteries through ligating the primary artery, and were therefore more difficult to control.

As to the engine getting out of order, the liability was very slight. It could be run by a child. It was much more simple than the sewing machine, and he should pity the doctor who could not use this engine. Of course, every device placed upon it made it a little more complicated, and it required study and practice to know how to work it. But if he had to remove a portion of the brain case he would not think of using any other instrument at the present time.

The Marriage of Syphilitics,—Dr. WILLIAM G. PORTER read a paper with this title, in which he said that perhaps no

more important or interesting question could have been submitted for discussion than that of the marriage of syphilities, and he confessed that he approached its consideration with an amount of diffidence which he would not have supposed to be possible some years ago. It would be very easy to dispose of the whole question by giving to patients who had been afflicted with syphilis, and who were contemplating matrimony, the celebrated advice of Mr. Punch to those about to be married, "Don'tt"

But in regard to this question we had a solemn duty to perform; on our decision might depend the future happiness and health, not only of the patient, but that of an innocent and virtuous woman and of children yet unborn.

The subject was so large in all its bearings that it would be simply impossible for him to more than outline some of its more salient points. In approaching the subject we must consider first the patient.

If we forbade him to marry, and he took our advice, we condemned him to perpetual celibacy—we robbed him of all the joys of matrimony, of possible paternity.

If we were right in our judgment, we had nothing with which to reproach ourselves.

But if we had acted unadvisedly; if he was really incapable of transmitting the disease to others; if he was capable of procreating healthy children; if he had a long life of health and usefulness before him; if, in other words, he was cured—we had done him a lasting injury, we had blighted his life, we had robbed the state of a citizen who would in all probability have been more useful married than single.

On the other hand, if we advised our patient who was or had been syphilitic that he could safely marry, and he followed our advice and infected his wife or procreated syphilitic children, we not only injured him, but inflicted irreparable injury on an innocent wife and helpless children.

Were there any rules, the speaker asked, which might guide us in the determination of this most important question? In the limited time at their disposal it would be impossible to offer the proofs of all the statements he would make; he would therefore endeavor to limit himself to propositions which he thought all could indorse.

In the first place, then, he would say that syphilis might be classified into three varieties—viz., the benignant, the moderate, and the malignant.

He supposed that, occasionally, all had seen cases of primary syphilis which had been followed by an exceedingly moderate amount of secondary symptoms, and then, almost without treatment, by perfect recovery and the absence of further manifestations; to these he would apply the name of benignant.

By moderate syphilis he meant those ordinary cases in which the disease ran through its various stages without severe symptoms—perfectly responsive to treatment, generally controlled by it, but which it might take many months or perhaps some years to cure.

By malignant syphilis he meant those cases which were severe from the start, in which the earliest secondary symptom might be a rupia with a profound cachexia, or immediately on the disappearance of the chancre, or even sometimes before it had disappeared, the nervous system of the patient might be profoundly affected.

Recognizing these three varieties, his next proposition was that all three forms were generally curable: the first exhausting itself, the two latter requiring the treatment of the skillful physician to overcome them, for there was no disease which responded more rapidly to proper treatment, or showed worse results when improperly treated, than syphilis.

We knew that syphilis was curable from the fact that many patients remained indefinitely without a recurrence of symptoms, and, more than all that, they not infrequently contracted it a second time. But up to the present time no means had been discovered by which we could say absolutely to any individual patient, "You are cured; you will never have a return of this disease unless you contract it again." Because of this, many writers on syphilis maintained that, as we could never say absolutely that a patient was cured, we had no moral right to advise him to take the chances of matrimony; that we could never tell, even after the lapse of years, when a relapse might occur, and the patient who had supposed himself to be cured might transmit to his posterity this terrible disease. It seemed to him that, if there was one thing established in medicine, it was the power of medical treatment over the manifestations of syphilis. Who had not seen symptoms disappear under treatment almost as if by magic, and cases apparently the most hopeless in which health had been restored? and yet it happened to all occasionally to see cases in which, in spite of systematic and long-continued treatment, there was persistent relapse. The patients were not really ill; they went about attending to business and the affairs of life as usual; and yet we knew and they knew that they were not well; the slightest indiscretion was sure to produce a temporary relapse, and so it went on for years and years. He thought that all who had been in practice for twenty-five years or more must recognize the fact that we did not see nearly as many severe cases of syphilis as we formerly had done, and yet, if we considered the numberless pathological conditions which it most assuredly caused, we must admit that it was still a most serious affection, and one which resulted much more frequently in death than was generally sup-

Under what, if any, circumstances were we justified in informing a patient who had suffered from this disease that it would be safe for him to marry?

In the first place, marriage should be absolutely forbidden to any patient who presented, at the time he consulted us, any of the symptoms of syphilis—primary, secondary, or tertiary. Dr. Porter then quoted from the master on this subject—Fournier:

"What, then, is marriage in its completeness, gentlemen? Marriage is not only an affair of sentiment, of passion, of convenience, and of interest. To consider it from a standpoint more practical and af the same time more elevated, marriage is an association freely entered into, where each contracting party is pledged to bring in good faith a share of health and physical vigor, with the view of co-operating, on the one hand, for the material prosperity of the family, and, on the other hand, for the raising of children, the supreme and sacred end of every union.

"Now, what in this case, I ask you, will be the share contributed to the partnership by a husband syphilitic, and not cured of his syphilis? His share will be that of a health compromised, hypothecated, burdened with a debt hereafter due to the pox, that pitiless creditor.

"On account of the pox it may happen that this man may experience one day or another such and such serious affections which will ruin his health, such and such an infirmity which will render him incapable of work, incapable of earning his daily bread; and then what will become of the family of which this man is the recognized support? What will become of his wife? What will become of his children?

"On account of the pox also this man may die. What may happen, he being dead, to his wife and to these children?

"Is it admissible, then, that a man should think of creating for himself a family when he is liable to fail this family? Is it

admissible, is it right, is it moral that a man should dream of having a wife and children when he offers the possible prospect of widowhood to this wife, of orphanage to these children, of poverty to this family? No, a hundred times No!

"Also, and I do not hesitate to say it, the man who is syphilitic and not cured of his syphilis, and fears not, nevertheless, to append his signature to the marriage contract, commits at this moment a base act, an act immoral and corrupt, an act which good people will be unanimous in condemning."

In the second place, Dr. Porter went on to say, marriage should be absolutely forbidden to all syphilitic patients who had not been subjected to a most thorough, complete, and prolonged treatment.

And finally, in the third place, before sanctioning the marriage of a syphilitic, the requirement of a sufficient treatment having been fulfilled, the physician should be satisfied that he was in perfect health, and that he had had no symptoms, even suspicions, of syphilis for a period of at least two years.

Under these circumstances and with these limitations he had no hesitation in telling patients that he thought they were reasonably safe in marrying, and he had never yet had reason to regret the advice which he had given.

Dr. J. WILLIAM WHITE said that he thought he agreed to the general conclusions of Dr. Porter's paper. The three forms he had mentioned were commonly met with in practice. It was certainly to-day more benign than when many of them had begun to practice medicine.\* It was now rare to see the grave variety in which the primary symptoms were soon followed by the tertiary phenomena. If it was true that syphilis was a milder disease than it used to be, it was milder probably in every direction, and we might feel more encouraged than our predecessors had been to authorize the marriage of syphilities. It had been many years before Dr. Agnew could be brought to say positively that he approved of the marriage of any of his syphilitic patients, and it might be that this slowness on his part had been due to the sort of experience with syphilis that younger men had not had.

It was desirable to formulate some safe rule as to the permission which we were asked to give or withhold in cases of syphilities intending marriage. The writers who have said that, as we did not know when a given patient was cured, and, as we could not apply any test which established this, we could not, therefore, give our consent, confuse the future danger of the individual with the possible danger to others, including his offspring. He thought it was a confusion which prevailed to a certain extent in the profession, and, to a very wide extent, in the laity. It was unfortunately true that we were not able to tell a man that he himself would not have further symptoms of syphilis. We might place the percentage of cures very high, and he himself thought that most of us who treated syphilis intelligently got from ninety to ninety-five per cent. of cures in the average line of cases. But we could not select from the hundred cases the five or ten cases that we had failed to cure, and forbid marriage. Nor could we expect to do so until bacteriology had done more for us than it had up to the present. But that had very little bearing, he thought, on the question of marriage. Because, as a matter of fact, after a certain time had elapsed, particularly after the combination of circumstances which existed where a patient had had moderate syphilis with efficient treatment, and had gone for a time, two years, say, without symptoms, he thought we were very safe in saying there was little danger to others. Personally, he would have the same, but no greater, objection to giving his consent to the marriage of a man with tertiary syphilis as to that of a man with strongly marked tubercular predisposition or with mental disease. He thought the risk of transmission in the two last

named would be far greater than if he had had gumma, rupia, or periosteal nodes. He was not aware of any instance, satisfactory to his mind, in which tertiary syphilis had been transmitted either to any individual or to offspring. The reported cases were generally defective in some important point. It was difficult, where two persons were concerned, particularly in instances of heredity, to be quite sure that the husband had been the parent, and most reported cases were at least open to error in that respect. There were other sources of error, but, as a matter of fact, the impression left on his mind was that there was no case scientifically conclusive as to the transmission of tertiary syphilis. He would therefore dissent absolutely from those who believed that no patient with any form of syphilis should be permitted to marry. A man with tertiary phenomena was not likely to have healthy children, nor was the tubercular patient, but the man with tertiary phenomena was not likely to have syphilitic children. And it was safe to say he could not transmit his disease. Even the fluid of his gumma, of his ecthyma, or of his softening node, could not be inoculated.

His wife might have an occasional miscarriage, or have a child born dead, just as might have happened if the husband had had chronic alcoholism, or had been in the last stage of any grave constitutional disturbance, but she was not likely to have a syphilitic child. That, he believed, was the only point in Dr. Porter's remarks on which he had any criticism to make. He thought his general rules were admirable. It would surely not do to say that all syphilities might not marry, because it would certainly result in ruining many lives. He was personally familiar with a great many persons in whom this unnecessary dread of syphilis had led to prolonged dissipation, or melancholia, or suicide. He was now treating a gentleman who had broken off his engagement with an attractive girl; he had given up his business and was gradually progressing toward the suicidal stage because he was of the opinion that no man had a right to marry with this disease. He was morbid, of course, and Dr. White thought he would probably come out of it. But there had no doubt been a great deal of unnecessary alarm. Dr. Porter's rules were practically those he had adopted, except that he did not require such a long period of freedom from the symptoms. In general figures, he told his patients they must wait four years. But if a man, at the end of three years, had a slight mucous patch he did not, on that account, make the time five years. During fifteen or eighteen years he had seen a great many of these cases, and he had from the start followed this general rule. Fournier's book had been published about 1878, and had been the first well-considered work on the subject which had come under his notice. He had been appointed a teacher on syphilis in the university, and he had practically adopted his rules then, and had never varied very much from them since. Fournier said in effect that syphilis must have been benign; that a period of three or four years must have elapsed; and that the treatment must have been thorough and complete. The speaker said he had never varied much from them, but as time had gone on he had come to place more and more weight on the one element of time, the period that had elapsed after inoculation, and comparatively less upon the thoroughness of treatment and absence of symptoms. And he need scarcely say that in that time there had been a great many patients who had grown up and married, and had had children, and he could not recall an instance where such a marriage had been entered into with his consent and approval where anything had happened to cause him to regret his action. He did not know a single case where, after four years had elapsed before marriage, there had been born a syphilitic child. He thought that was, after all, the most important thing to discuss. If it was a safe rule, it was an easy one, and we could not go far wrong in its application. If it was not a safe rule he should be glad to hear reasons for considering it unsafe.

Dr. EDWARD MARTIN said that the subject had been very thoroughly traversed by Dr. Porter, Dr. White, and others. The rules governing it were practically common-sense rules dependent upon certain generally accepted facts. Thus every one granted that a man with syphilis not two years old was likely to give the disease to his wife, and to have diseased children, though this was a rule with mary exceptions. It was also granted that a man with syphilis three or four years old was not likely to convey or transmit the disease, though this rule had a few exceptions. It was granted that a man with syphilis more than four years old was not necessarily cured, since it was impossible to state positively that late manifestations would not appear, but in so far as conveyance of the disease to others was concerned, he could be regarded as safe. This was a rule with very rare and doubtful exceptions. All the reported cases were open to the criticism of Dr. White. The evidence was, however, rather strong to the effect that the disease could be transmitted to the child when it was impossible to infect the wife directly. Finally, it was granted that syphilis was a curable disease, though there was absolutely no sign or group of symptoms which could be taken as satisfactory evidence of cure. Reasoning from these rudimentary and commonly accepted beliefs, it would seem perfectly proper to allow syphilities to marry after their disease had become non-contagious. Probably after two years of continued careful treatment the disease ceased to be contagious in the majority of cases. Not always, however, and it was proper to err on the safe side. The period of four years was that generally allowed, and he had never known a physician who had seen or heard of a case of transmission after this period. Even after four years marriage might not be advisable, not because a patient had had syphilis, or was likely to infect others, but simply because of debility or cachexia there was little promise of healthy offspring. The ground for forbidding marriage would be precisely that taken in the case of consumption. There was an exception which he had made to the general rule of forbidding marriage till the contagious stage of syphilis was passed. Although marriage perhaps had had for its cardinal purpose, and had still, the propagation of the species, there were many other reasons why it was entered into. There was the element of association, protection, and mutual interest which could be considered quite aside from the sexual aspect of the case. 'It happened, he thought, to almost every one, to see cases of buccal chancre acquired by innocent girls from their affianced. He had never hesitated under such circumstances to encourage marriage, warning the patients thoroughly of the dangers of conception till at least four years should have elapsed. With this one exception, he believed he was thoroughly in accord with the rules laid down by Dr. Porter and Dr. White.

Dr. Aethur Van Harlingen said that the remarks he had to make were based only upon his own personal experience. Any man practiced in this class of disease, if he had kept careful note of his cases, must have a certain aggregation of personal experience, and he thought that when we brought this experience together it was of a certain amount of value. When the subject of this discussion had first been brought to his notice he had begun to look up the literature, and had found that Fournier's work was practically the only one which could be used for reference. In an article written several years ago he had based his observations on the work of another French writer, Lancereaux, which he had thought excellent from a practical point of view. Fournier, however, was the only author who had given us statistics upon which we could base any conclusions. Aside from this, he thought our individual experi-

ence was all we could depend upon. The result of his own experience was as follows:

It did not seem proper for a man to marry as long as he had any of the secondary symptoms, though he had known immunity to result even in these cases. In his own experience, tertiary symptoms had never proved contagious. The man who married with the secondary symptoms ran the risk of conveying the disease to his wife. With tertiary symptoms he could not recall any cases in which a man had given syphilis to his wife. In regard to the conveyance of the disease to the child, it had been said that it was possible for a man, who was in that stage in which the lesions were in all probability not contagious, to convey syphilis to the offspring, but he could not remember any cases in which this had been actually reported. He thought it would be advantageous, if any such cases existed, that they should be recorded. Fournier recorded from sixty to seventy cases of syphilities who had married at periods extending from nine to twelve months to a number of years. He reported one case in which the man, having syphilis, had married, and after having three or four healthy children he had suffered from tertiary symptoms. His wife had not been infected. He had watched two dozen cases, and had followed some from five to twenty years, and he should not fear any of his patients' marrying after the second year, if they had submitted to a regular course of treatment. He had been in favor of the continuous treatment. His custom had always been to wait until the secondary symptoms occurred, and treat continuously. He had treated a dozen or twenty cases from eighteen months to three years. He could not remember any case in which he had authorized marriage after the second year where the disease had been transmitted. He was aware that this was a much shorter time than was allowed. His own experience was that, after the second year, healthy children could be engendered. Perhaps the standpoint taken by others was a safer one than that which he had taken. He thought it would not be very long before some such question would come up before one of our courts of justice. It seemed to him a question that could only be decided by uniting our experience, and by each person in private practice publishing his own well-recorded cases. His urgent advice was that those who saw such cases should record and publish them. He could not see any other way of securing proper data.

He remembered the case of a young gentleman who had shown the late ulcerative symptoms of syphilis, which had yielded very quickly to proper treatment. After the ulcerative . lesions had passed away he had suffered from that peculiar form of myositis resulting in the contraction of the biceps, which had yielded to some extent to treatment, but not entirely. He always had had a certain amount of contraction. After eighteen months of treatment he had asked the speaker if he would allow him to marry. He said he would think it over for several months and then give him his opinion. He did not come back for that opinion. But if he had, and if the speaker had given his consent, the case might have been brought up before the courts. He wondered what his position would have been if this gentleman had married; if he had given him a written opinion that he would in all probability not transmit the disease to his wife nor have a syphilitic child, and then if the worst had happened? What would have been the expert testimony given by his colleagues? He thought that if we could get a body of personal experiences from the gentlemen who see these cases, accurately gathered together, we should have something to go upon. There was really nothing in print except this book of Fournier's. If a case such as he had mentioned were to come before the courts, he did not know what he would have to base his opinion on, except what had been said. He thought it was one of those questions in which the

members of the college should publish their opinions, and this he thought would make a body of evidence which would be of use later on

later on. Dr. Henry W. Stelwagon said he had listened with a great deal of interest to the reading of Dr. Porter's paper and the remarks by the other gentlemen who had spoken. It was a subject, of course, of very large importance and far-reaching. It seemed to him in a question of this kind that an opinion was to be reached only after viewing it in all its aspects and bearings, basing the conclusion upon aggregate observations, and not putting too much weight upon individual experience. There were certain facts upon which he thought all observers were fairly well agreed. One was, that during the active and early stages of the disease marriage was tolerably sure to be followed by dire consequences. Another was, that under the most favorable circumstances at least two years should have elapsed between the contraction of the disease and the assumption of the marriage state. Another was, that after a variable number of years syphilis tended in almost all cases, and probably sooner or later in all cases, to lose its infective activity and transmissibility, so that finally there remained nothing of a specific character to transmit. This length of time depended doubtless upon several factors: the type of the disease, which Dr. Porter had referred to, the prior and concomitant health of the individual, his mode of life, and last, but probably the most important of all, the character and thoroughness of the treatment. In syphilis of a grave type, those cases which we saw from time to time of a more or less malignant character, the greater possibility of present and future risk should not be lost sight of. The same could be said of the disease occurring in strumous individuals and in other persons in delicate health. The syphilitic addicted to the excessive use of alcohol for a long time was doubtless an unsafe husband and procreator. The explanation was to be found in the lessened resisting power. With the exception of these several classes, however, he believed that syphilis was not the grave misfortune it had so often been painted. In the average case of syphilis, occurring in a subject of ordinarily good health, living a temperate life, and who had had intelligent treatment, the power to communicate and transmit the disease was probably, with the exception of a few instances, lost in the course of a few years; and even in the imperfectly treated and neglected cases, judging by general experience, the disease would seem to wear itself out in from two to five years. If this had not been the fact, the examples of hereditary transmission would certainly be much more numerous than observations showed them actually to be. It was, however, the uncertain cases, or the exceptional cases he would say, which gave us concern and made us hesitate. And such cases, we were informed by the records, might occur in those who had been well treated and had carried out all medical directions, and who were or should be presumably entirely free from all contaminating virus. That such exceptions, according to the records, did occur we must all concede; that they were extremely rare must likewise be granted. It had often occurred to him that some of these exceptions were apparent rather than real, that there might have been good and sufficient reasons pointing against marriage, such as an insufficiently long period of treatment, depraved general health, and alcoholism; some might also be attributed to faulty observations, as Dr. White had suggested. He believed himself that persons in good health, of good habits, in whom the disease had been of a mild or average type and had run a favorable course, with no tendency to active recrudescence, and whose treatment had extended over a period of two or three years, during the last year of which there had been no manifestations—that such persons might, if three years or more had

elapsed since the date of the contraction of the disease, marry without the slightest risk. Such was the conclusion to which his own observations would lead.

[N. Y. MED. JOTR.,

If, however, the question of the marriage of syphilities was to be viewed purely from a strictly scientific and medical standpoint, and thus cognizance necessarily taken of the rare exceptions and the possibility of disaster recognized, we should probably feel obliged to refuse our professional permission in all cases. But by so doing we would prevent many happy marriages, damage the socially and politically important family life, and tend, moreover, to encourage immoral living. A liberal view of the question, based upon the broad ground of the public welfare and the knowledge that in proper cases the danger was practically nil, would not justify us in such a course.

Dr. A. B. Hirsh said that there was one phase of the subject which had a half-medical, half-popular aspect, that might be appropriate to mention, and he referred to a point raised in the discussion by Dr. White—that of syphilomania as occurring in some of the chronic cases coming under our care. We were quite well aware that such cases were apt to occur in the intellectual patient, the man who read, and not in the average or ignorant dispensary class; such individuals would be apt to have this subject laid open to their inspection by novelists who dealt with the more material subjects of the day. It was quite interesting in this connection to know that one of the works which had been most widely read recently dealt with this very subject, and individuals suffering from this infection and reading the book would perhaps be confirmed in this very serious view of the subject, and be liable to the mania here discussed.

Dr. Porter said that Dr. White seemed to intimate that he himself possibly thought the tertiary lesions were contagious. He had had no such thought at all, but put tertiary patients under the ban, not on account of transmitting the disease, but on account of their generally broken down condition of health, which would not justify marriage.

In regard to the time, the rule which he had laid down which had guided him for a number of years was to allow two years to elapse after the disappearance of the last syphilitic symptom. The average period of the duration of treatment was about two years, and that would make the duration of the time laid down by Fournier four years after the inception of the disease. Many cases, however, did well in which the treatment was not prolonged more than a year. At the end of that time, after two years had elapsed, that would make the period three years, The time depended on each individual case.

In regard to statistics, Dr. Van Harlingen had well said that the only thing we knew of in the literature on this subject had been written by Fournier, and these statistics, as well as those given by other writers, were very misleading, because it was only within comparatively recent years that syphilis had been so systematically treated as it was to-day, and certainly many of the cases of alleged reappearance of symptoms many years afterward could be explained on the ground of insufficient treatment. He thought that statistics could be collected of the modern methods of treatment of syphilis that would show much more favorable results than older statistics.

## Miscellany.

Bladder Gymnastics and Irrigation.—We are indebted to the Buffulo Medical and Surgical Journal for advance proofsheets of an article thus entitled by Dr. Byron H. Daggett, of Buffalo, N. Y.

At the regular meeting of the Lake Erie Medical Association, July 15, 1892, says Dr. Daggett, I read an article describing a method of irrigation of the deep urethra and bladder without the use of a catheter, which was published in the Buffalo Medical and Surgical Journal, March, 1892. After the lapse of nearly two years' time, and the additional experience of continual tests, I feel warranted in asserting that nineteen out of twenty patients may be taught to irrigate in this way. The failures will be due to a very small stricture or a very large prostate.

I will briefly refer to a few notes taken since the publication of that paper, and preface these memoranda by repeating the technique of bladder irrigation without catheterization. The materials are a four-quart bag, a tube six feet long with a shutoff within easy reach. The tube is attached to the inlet of the double cannula, its bore being twenty per cent. larger than that of the outlet. The nozzle of the cannula is introduced from one to two inches, according to the size of the meatus, and is made wedge-shaped, in order to fill the varying calibers of urethral meati. It is sufficiently long to be conveniently held in place by grasping the penis behind the glans, at the same time drawing the pendulous portion in line with the fixed urethra. The bag is filled with water, at a temperature of 115° F., to insure more than blood warmth as it flows, and is made bland by the addition of a little glycerin, mucilage, or a few grains of salt or sodium carbonate, and elevated two or three feet above the plane of the pelvis.

The patient must assume a reclining position-a reversed squatting posture-since flexure and gravity are essential factors. He may do this in an ordinary bath tub by resting his back along the incline at his head, so that the trunk is at an angle of forty-five degrees from the horizontal line, flexing the thighs at right angles with the body and supporting the legs at right angles with the thighs. If there is no bath tub at hand a hip bath may be arranged for this purpose, or the patient may posture himself in a low rocking chair, tilted and blocked, so that the body assumes the position described, the legs resting upon another chair or upon a stand.

The nozzle of the irrigator is then introduced, the penis grasped and drawn in line with the fixed urethra, the stop opened, and the water allowed to run, if necessary, until the bag is empty; if it has not passed into the bladder, try again. A peculiar feeling gives warning of the passing of the water through the posterior urethra, the return flow diminishes and escapes in a pulsating stream, when a finger of the right hand is placed over the exit, to divert the entire flow into the bladder, which at first resents the intrusion and ejects after receiving two to three ounces. Repeat this and the bladder becomes more tolerant each time. Three to four flushings are sufficient at each séance, and the séances may be repeated three times daily if necessary. The novelty and comfort afforded by irrigation sometimes induce patients to overdo at the beginning before tolerance is established. The diminished, pulsating outflow would seem to indicate an anti- or retro-peristaltic action of the accelerator muscle. This process is a coaxing one, in which the gentle pressure of the continuous flow of the hot, non-irritating current and the posture described are essential conditions. The patient acquires a knack at the first success which he realizes, and which I can scarcely describe, that gives him an abiding faith in his ability to flush his bladder at will.

The Action of Iodide of Rubidium.—At a recent meeting of the Société de thérapeutique, a report of which is published in

that iodide of rubidium had not much taste and was well tolerated-two advantages for which he recommended it. He had seen it well borne by three patients who could not tolerate potassium iodide. In one of them the symptoms were ameliorated and abbreviated. It remained to be seen if, in syphilis, for example, the specific action was comparable to that of the alkaline iodides. On this point there was a doubt. M. C. Paul recalled the analogy between these facts and the fruitless trials of sodium iodide; this was well tolerated, but did not produce an effect equivalent to that of potassium iodide in the atheromatous. Moreover, this intolerance had been recognized, the author believed, if not always, at least sometimes, when this salt had been given in a diuretic infusion of corn silk. M. Bardet also mentioned that, in cerebral syphilis, this iodide had been known to succeed where the iodide of ethylforminine had failed. In scrofula, iodine itself should be prescribed, and not the alkaline iodides. M. Blondel said that an alkaline iodide combined in a solution with sodium bicarbonate was better tolerated than when taken alone. He said that the intolerance was more marked when the iodic salt was given before eating, and also when given in large doses. The rule should be to administer, in equal parts, the alkaline iodide and sodium bicarbonate. M. Jullien also had observed the intolerance of the organism for potassium iodide. M. Paul recommended the following preparations: 1. Wine of cinchona, nine ounces and a half; tincture of bitter orange peel, two drachms and a half; potassium iodide, one drachm. From one to two tablespoonfuls a day to be taken. 2. Svrup of roasted coffee, sixteen ounces and a half; potassium iodide, two drachms. The same doses daily. In this case it was a question of iodo-tannic preparations, the tolerance of which had been recognized for a long time.

An Eruption on the Palms of the Hands following the Administration of Antipyrine.—At a recent meeting of the Société de médecine et de chirurgie pratiques, a report of which is published in the Progrès médical for May 19th, M. Fournier made the following communication: A man who had had syphilis for a long time consulted him with regard to an eruption on the palms of his hands which had every appearance of syphilide. The eruption disappeared, and the patient was put on antisyphilitic treatment. A month later the symptoms reappeared, but on one of the fine, scaly elevations there was a vesicle of a reddish color, like that of ham. M. Fournier, not recognizing any syphilitic symptoms, made an inquiry, and found that the patient had taken, the day before, eight grains of antipyrine. He had also taken a similar dose before the preceding eruption, and again the same quantity later on. Four hours after having taken the antipyrine, the patient had noticed the same patches, which simulated palmar syphilis, on the palms of his hands. M. Morel-Lavallée said that these eruptions often had a syphiloid appearance, and generally affected the same spot in the same persons. M. Julien asked if the patient had had at any other time a true palmar syphilide, which had been brought back by the antipyrine, or whether the eruption was due only to the antipyrine. M. Fournier said that his patient had really had a palmar syphilide, but it was to him a matter of doubt whether the eruption was not caused by the antipyrine.

Glycosuria following the Administration of Thyreoid Extract.—In the British Journal of Dermatology for June, Dr. W. Dale James, of Sheffield, relates the case of a man, fortyfive years old, the subject of psoriasis, who had taken thyreoid extract without producing any effect on the disease, probably owing to the small doses swallowed-one tabloid twice a day. On March 22d he had begun to take four tabloids daily, and at the Journal des praticiens for May 19th, M. C. Vogt remarked the end of a week had complained greatly of depression, with

frequent flushings and palpitations, "his pulse beating all over him." The nervous symptoms had increased and he felt and looked like a very old man. Before another week had elapsed his thirst had become unquenchable, the quantity of urine had greatly increased, the breathing had become embarrassed, the pulse had risen to 132 a minute, and acetone was detected in the breath. On April 4th the urine had the specific gravity of 1.032, and sugar was freely found by all tests. The use of thyreoid extract was at once stopped, and a diabetic diet adopted; the quantity of sugar decreased daily, and on April 13th it could not be detected. The general condition of the patient had steadily improved, and on April 30th he was quite well, except for the psoriasis, which had not been improved by the treatment. This is, the author says, so far as he has been able to ascertain, the first reported case of glycosuria following the administration of thyreoid extract, although polyuria has been noticed more than once.

Proposed Variations of the Operation of Symphysiotomy.

-At a meeting of the Gynæcological Section of the Eleventh Congress of Russian Physicians, held in St. Petersburg in December, 1893, a report of which appears in the Centralblatt für Gynäkologie for June 9th, Dr. Fenomenoff read a paper in which he remarked that, inasmuch as after the operation of symphysiotomy the pelvis returned to its original narrowness, the possibility of being obliged to resort to a second operation on a subsequent occasion was not done away with. With a view to preserving the amplitude of the pelvis obtained during the operation the author had had the idea of maintaining the separation between the cut ends of the two pubic bones by inserting a piece of bone between them. He described two methods of performing this operation. 1. By the first method a cutaneous incision was made beginning a finger-breadth above the upper border of the pubic bone, on a line with the pubic tubercle, or between the latter and the external inguinal ring. The incision is carried in a crescentic form to the corresponding point on the other side, the convexity being directed downward and extending to the neighborhood of the lower border of the symphysis. In this way a flap is made which is easily raised, Thus on either side of the symphysis, from 2 to 2.25 centimetres from the median line, an incision is made through the periosteum down to the bone. The two incisions begin at the upper border of the symphysis and join each other below. Thus there is formed a triangle the base of which is constituted by the upper border of the symphysis, and the apex of which corresponds to the ligamentum arcuatum. After the periosteum has been raised to a certain extent a corresponding bony flap having the symphysis for its middle point is formed by means of a chisel or saw. Then the delivery is to be proceeded with. After its completion the periosteum is to be loosened from the lower half of the bony flap, and the corresponding bony base to be separated with a bone-forceps and forced downward in such a manner that the upper border of the flap comes to be situated at the point originally occupied by the middle of the symphysis; consequently the two pubic bones must be separated from each other at this situation to the extent of from 2 to 2.5 centimetres, thus notably increasing all the pelvic dimensions except the distantia Litzmanni, which is somewhat shortened.

2. In the second form the cutaneous incision is the same as in the first. The bones are sawed through in a parallel direction on the two sides. The section begins very much as in the preceding method, but ends at the level of the center of the symphysis. The two vertical sections are connected with each other at this level by a transverse section. Thus there is formed an oblong quadrangular bony flap from 4 to 45 centimetres long and of a width equal to half the height of the symphysis.

This flap is held upward and thereupon the ordinary operation of symphysiotomy is completed upon the lower half of the symphysis. After the conclusion of labor the bony flap formed of the upper half of the symphysis is brought down and forced between the cut surfaces of the lower half of the symphysis. The amplification of the pelvic dimensions is a little greater by this method than by the other.

The author stated that this operation had been performed a few times on the dead body and on animals, and that dogs bore it very well. The account concludes with the statement that the reading of the paper was followed by a lively discussion.

Sodium Nitrite as a Therapeutic Agent.-The Practitioner for May contains an article on this subject by Dr. Gordon Sharp, of Edinburgh, in which he relates his experience with this nitrite. Sodium nitrite, he says, is comparatively stable, and its solubility renders it most useful and easy of administration. It can not be inhaled, but it has the great advantage of relaxing all the vessels. It has been stated that sodium nitrite affects chiefly the vessels of the upper half of the body, but in the author's experience the dilatation has been a general one. With regard to the dose, the author states that from twelve to twenty grains have been given in epilepsy, but he does not believe that the salts were pure, as much smaller doses are apt to cause alarming symptoms, such as nausea and syncope. After an extensive experience with this salt, he concludes that from two to five grains are quite enough, and that from one to four grains would be a better standard. During the administration of the salt, in a large number of cases, the patients showed such symptoms as vomiting, syncope, and headache. These are due to the rapidity with which the blood pressure is lowered, and the following mixture is used by Dr. Gordon as a primary stimulant and sedative: Fifteen-minim doses of aromatic spirit of ammonia with one or two minims of tincture of capsicum; five minims of solution of hydrochloride of morphine, and chloroform water to half a fluidounce.

In all respiratory affections the author has been struck with the difficulty of producing the physiological effect of the nitrites on the pulse, as tested by the finger. For example, in bronchitis three grains of sodium nitrite may be given four times a day and continued for two or more days without the pulse revealing any softening when examined by the finger; while the same dose given in a case of angina pectoris or irregular heart action, without any prominent additional respiratory affection, would cause a marked change in the character of the pulse after one or two doses. Dr. Gordon relates a number of cases in which sodium nitrite had been employed, from which the following conclusions may be drawn: 1. Sodium nitrite, being stable, may replace the less stable amyl and ethyl nitrites. 2. It dilates all the arterioles rapidly, and so relieves the heart quickly. 3. Disagreeable symptoms may be overcome by combining it with ammonia water or spirit of chloroform and small doses of morphine. 4. It is most useful in anginal affections and in irregular heart action. 5. To obtain the most benefit from its use it should be continued some time after all symptoms have passed away. By this means the heart is able to regain its tone and so to repair itself. 6. The maximum dose is four, or at the most, five grains, and generally one or two are enough. 7. Graves's disease would appear to be aggravated by it. 8. Bronchitis and asthma, in the author's experience, are not benefited by its use.

Sulphonal in the Treatment of Whooping-cough.—The June number of the *Practitioner* contains the following prescription: Sulphonal, one grain; creasote, two minims; syrup of tolu, water, each, two ounces. Two teaspoonfuls of this mixture are to be given every two hours.

# New York Medical Journal.

A WEEKLY REVIEW OF MEDICINE.

EDITED BY

FRANK P. FOSTER, M.D.

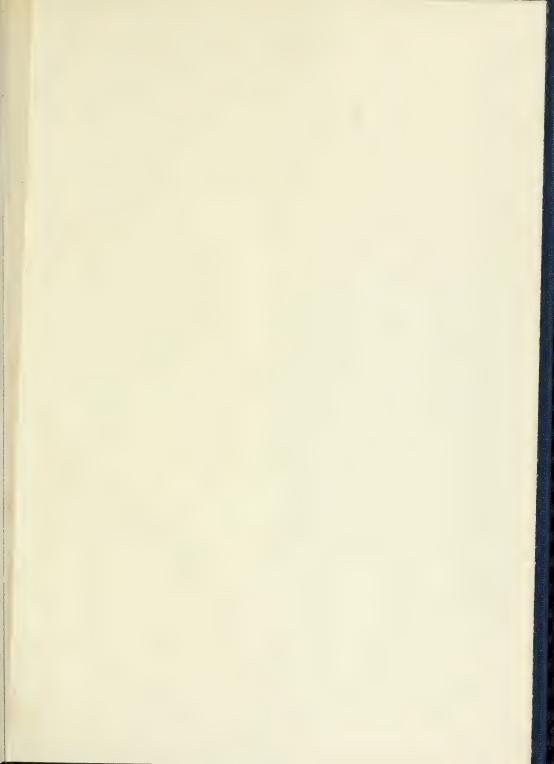

THE PHYSICIAN who would keep abreast with the advances in medical science must read a live weekly medical journal, in which scientific facts are presented in a clear manner; one for which the articles are written by men of learning, and by those who are good and accurate observers; a journal that is stripped of every feature irrelevant to medical science, and gives evidence of being carefully and conscientiously edited; one that bears upon every page the stamp of desire to elevate the standard of the profession of medicine. Such a journal fulfills its mission—that of educator—to the highest degree, for not only does it inform its readers of all that is new in theory and practice, but, by means of its correct editing, instructs them in the very important yet much-neglected art of expressing their thoughts and ideas in a clear and correct manner. Too much stress can not be laid upon this feature, so utterly ignored by the "average" medical periodical.

Without making invidious comparisons, it can be truthfully stated that no medical journal in this country occupies the place, in these particulars, that is held by The New York Medical Journal. No other journal is edited with the care that is bestowed on this; none contains articles of such high scientific value, coming as they do from the pens of the brightest and most learned medical men of America. A glance at the list of contributors to any volume, or an examination of any issue of the Journal, will attest the truth of these statements. It is a journal for the masses of the profession, for the country as well as for the city practitioner; it covers the entire range of medicine and surgery. A very important feature of the Journal is the number and character of its illustrations, which are unequaled by those of any other journal in the world. They appear in frequent issues, whenever called for by the article which they accompany, and no expense is spared to make them of superior excellence.

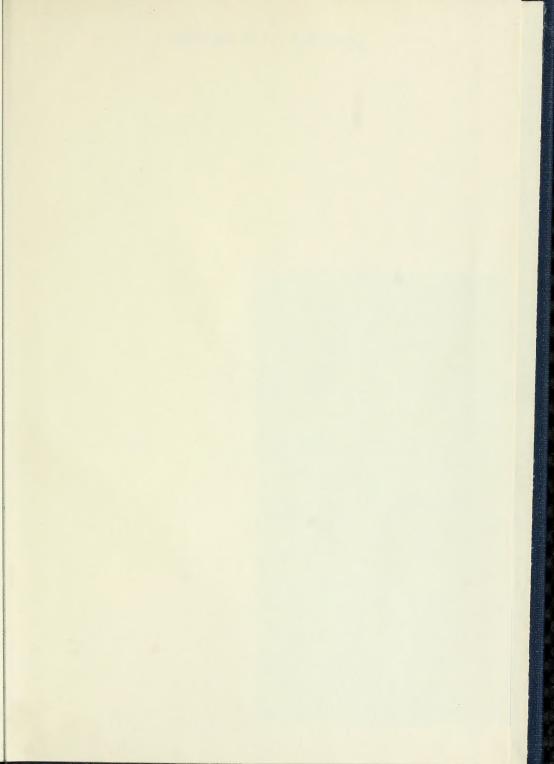

Subscription price, \$5.00 per annum. Volumes begin in January and July.
